BEER PRODUCTION AND CONSUMPTION IN GERMANY.—According to the latest statistical reports on the subject, Germany has now lost the first place among beer-producing countries to the United States. In the year 1907 Germany stood easily first, with a production of 1,947 million gallons. In 1909, however, the United States produced 1,873 million gallons, while Germany came second with 1,815 million gallons. The production of the other leading countries in 1909 was as follows: United Kingdom, 1,237 million gallons; Austria-Hungary, 501 million gallons; France, 290 million gallons. Germany exports beer principally to Belgium, the United Kingdom, France, Austria and Switzerland, while it imports from Austria, and small quantities from England. The consumption of beer has steadily decreased since 1900, when it was 31 gallons per caput (in Bavaria 65¼ gallons), while in 1909 the consumption was not quite 26½ gallons per caput (Bavaria 60¾ gallons), so that the consumption per caput in Germany has decreased more than 4½ gallons in the decade.

NATIONAL CONGRESS OF ITALIAN OLIVE GROWERS.—The National Congress of Italian Olive Growers was held last month at Porto-Maurizio (Liguria). The subjects discussed were: 1. The olive and other oil-producing plants; 2. The production and commerce of the table olive; 3. Pruning as a means of regulating the production; 4. Fiscal tariffs in relation to the oil industry; 5. Advantages of co-operation with regard to the cultivation of oleaginous plants and the oil industry; 6. Diseases of the olive-tree and legislation required for their prevention. Many interesting papers were read during the congress, and excursions made in the surrounding district, including one to France to visit the oil-works of the Société du Moulin Co-operative at Levens, where the members were entertained at a banquet. A general opinion appears to prevail, both in France and Italy at the present time, that more drastic measures should be taken by the Governments to prevent the spread of the parasite which infests the olive-tree, and to which the bad harvests of late years may be attributed.

IMPORTS OF WALNUTS TO BOHEMIA.—The Italian consul at Prague reports that the importation of walnuts to Bohemia is considerable. Prague alone receives annually from 1,000 to 2,000 tons, which are sent chiefly from Grenoble. The two kinds, locally known as *markos* and *cornes*—a small, thick-shelled variety—find a ready sale throughout the country, if clean shelled and put up in sacks containing two hundredweight.

CANTOR LECTURES.

THE APPLICATIONS OF ELECTRIC HEATING.

By Professor J. A. FLEMING, M.A., D.Sc., F.R.S., M.Inst.E.E.,

Pender Professor of Electrical Engineering in the University of London.

Lecture I.—Delivered March 6th, 1911.

THE LAWS OF ELECTRIC HEATING, RADIATION, AND THERMOMETRY.

The applications of electric heating have become so numerous and important that, although the subject is not entirely novel, there is much of sufficient interest in it to justify its selection as a topic for a course of Cantor Lectures.

Everyone is aware that an electric current creates heat in its conductor. We have the evidence before our eyes in every electric lamp and radiator. Indeed, so common is the knowledge of this fact that when any building takes fire the first instinct of the daily journalist is to ascribe it to the "overheating of the electric wires," although, if the truth were known, the actual cause of the conflagration may have been something quite different. An electric current makes itself evident to us, however, only by the physical effects it produces, and the chief of these are the production of heat in the conductor, of magnetic force around it, and of chemical decomposition in it when it consists of certain liquids. It therefore becomes possible to measure it by the amount of these physical changes it produces, and to express its value in terms of an appropriate unit. We shall not stop to discuss the relative advantages of defining the unit of current thermally, magnetically, or electro-chemically, but simply call to mind the definition of the unit current called the *ampere* as settled and defined by the International Conference on Electric Units and Standards which met in London in October, 1908. It is as follows:—"The ampere is the name for an unvarying unidirectional current of electricity which, when passed through a neutral aqueous solution of nitrate of silver containing fifteen to twenty parts of the dry salt by weight in one hundred parts of water by means of a silver anode and platinum cathode, deposits silver at the rate of 0·00111800 grain per second or 4·0248 grains per hour." This is equivalent to about one ounce in seven hours. This current is a close approximation to one-tenth part of the absolute electro-magnetic unit of current which is defined as the current, unit length of which acts on a unit magnetic pole at a unit of distance with a unit of force (one dyne).

The first question which meets us then is the inquiry as to the amount of heat produced in any conductor by currents of given and various strengths. J. P. Joule proved in 1841, by careful experiments, that for the same conductor the total heat produced by a current varies as the time and as the square of the current. Also the same current passed through various conductors generates heat in them at a rate depending on the dimensions and on the material of the conductor. Taking these conductors in the form of wires or cylinders, the heat produced by unit current varies as the length, inversely as the section, and proportionately to a constant called the specific resistance or resistivity of the material. Combining these statements into a single symbolical one, we have the rule commonly known as Joule's law, which, symbolically expressed, is

$$H = C^2 Rt, = \frac{C^2 \rho l t}{s},$$

H being the heat produced in a time t by the current C in a resistance R, or wire of resistivity ρ, length l, and section s.

It is then necessary to define our units of heat and energy.

The scientific unit of heat is the *calorie*, which is the heat required to raise one gramme of water 1° C. in the neighbourhood of 10° C., or to raise it from 10° C. to 11° C.

The ordinary engineering unit is the British thermal unit (B.Th.U.), which is the heat required to raise one pound of water 1° F. in the neighbourhood of 60° F., or from 60° F. to 61° F. One B.Th.U. is, therefore, nearly equal to 252 calories.

The scientific unit of energy is called one joule, and is ten million times the work done in overcoming a force of one dyne through one centimetre.

The ordinary engineering unit of work is the foot-pound, which is a gravitation unit, and therefore must be specified for a particular locality. Careful experiments by Joule, Rowland, Griffiths, and others, have shown that the amount of heat called the calorie is mechanically equivalent to 4·2 joules, and therefore one B.Th.U. is equivalent to 777 foot-pounds at Manchester, or to 1,058 joules. Lastly, we have a unit of work or energy called one kelvin, or one Board of Trade unit (1 B.T.U.), equal to 3,600,000 joules, or to one kilowatt continued for an hour, or to 1,000 watt-hours. The relations of these various units of heat and energy are exhibited in Table I. below:—

TABLE I.

UNITS OF FORCE, WORK, POWER, AND HEAT, AND THEIR EQUIVALENTS.

1 dyne = the force required to give a mass of 1 gramme a velocity of 1 centimetre per second after acting on it for 1 second.

1 gramme-weight = 981 dynes (at London).

1 erg = work done when a force of 1 dyne is overcome through 1 centimetre.

1 joule = 10 million ergs = 0·7373 foot-pounds.

1 foot-pound = work done when a weight of 1 lb. is lifted 1 foot high against gravity = 1·356 joules.

1 watt = work of 1 joule performed per second.

1 kilowatt = 1,000 watts.

1 kelvin = 1,000 watt-hours = 3·6 million joules.

1 horse-power = 746 watts = 550 foot-pounds per second.

1 calorie = heat required to raise 1 gramme of water 1° C., mechanically equivalent to 4·2 joules or 3·1 foot-pounds.

1 British thermal unit = heat required to raise 1 pound of water 1° F.; mechanically equivalent to 1,058 joules or 780 foot-pounds = 0·294 watt-hour.

1 kelvin = 3,402 B.Th.U. = 857,143 calories.
= 18 pints of water raised from 60° F. to 212° F.

At the outset it is necessary to distinguish carefully between heat and temperature. The temperature of a body is a quality of it in virtue of which it tends to take up or give out heat to other bodies. Two bodies are said to be at the same temperature if, when put in contact with each other, no heat passes from one to the other; and similarly their difference of temperature is a measure of the tendency of heat so to pass. Since addition of heat to a body is, in most cases, associated with a rise in temperature, and with certain other physical effects such as expansion in volume, change in electrical resistance, or change in pressure, we are able to construct instruments called *thermometers*, which enable us to compare temperatures, as well as instruments called *calorimeters*, which enable us to measure quantities of heat.

The ordinary mercury-in-glass thermometer is an appliance by which we test the temperature of a body by means of the visible relative bulk expansion of mercury in glass, as shown by the rise and fall of the mercury in the stem.

There are certain physical changes, such as the melting and boiling-points of various bodies, which always take place at identically the same temperatures, and hence give us what are called *fixed points* of temperature. To obtain a scale of temperature we have to assume certain numerical values for two of these temperatures, and divide the interval in an arbitrary manner. Thus, if we take 0 to represent the melting-point of ice, and 100 that of the steam of water boiling under 760 mm. barometric pressure, and divide the interval into 100 degrees, we obtain the Centigrade scale, which is continued below 0° C. and above 100° C. with equal intervals.

This mode of constructing a temperature scale is perfectly arbitrary. Two mercury-in-glass thermometers made with different qualities of glass and agreeing in temperature reading at the fixed points will not necessarily agree in their readings at intermediate points, owing to the differences in the law of expansion of the two glasses. A better scale is obtained by employing the change in pressure of a constant volume of one of the gases with very low boiling-point, such as hydrogen or nitrogen. A given volume of these gases increases in pressure between 0° C. and 100° in very nearly the ratio of 273:373. Hence a degree of temperature may be defined as the increment of temperature which increases the pressure of a unit of volume of hydrogen or nitrogen by an amount equal to $\frac{1}{273}$ of its pressure at 0° C.

If the gas followed the same law of pressure-variation without change of state as the temperature continually decreases, it is obvious that the

pressure would vanish entirely at 273 degrees below the melting-point of ice. This temperature is therefore called the absolute zero on the constant-volume gas thermometer, and temperatures reckoned from this point are called absolute temperatures. The slight variations in the coefficients of expansion of different gases, and of the vessels in which they are contained, makes this gas scale also an arbitrary one, so that temperatures have to be defined by reference to some standard air thermometer such as the constant-volume nitrogen thermometer, which is the standard of reference at the International Bureau of Weights and Measures at Sèvres, near Paris. Lord Kelvin suggested, however, in 1848, in the *Philosophical Magazine*, a method of defining temperature without reference to any particular substance, which is based on thermodynamic considerations, and at the same time showed that there must be an absolute zero of temperature which was found to coincide closely with the absolute zero as defined by the constant-volume gas thermometer.

Experiment proves that whilst we can convert the whole of any quantity of mechanical work into heat, as, for instance, when a train is stopped by its brakes, we cannot in general convert the whole of any quantity of heat into mechanical work. We can only convert part of it, whilst at the same time some other part must be lowered in temperature. Thus an engine takes steam from a boiler at a high temperature. The steam, after use in the engine, is given up to the air or to the condenser at a lower temperature, and part of the heat originally in it disappears as heat, but the equivalent energy is obtained as mechanical work done by the engine. If the engine is a reversible one—that is, can not only be used to convert heat into work, but work into heat—then its efficiency of conversion for heat into work is easily shown to be a maximum, and to depend only upon the temperature of the source of heat and upon that of the condenser or sink. Lord Kelvin proposed to define the temperature of the source and sink or furnace and condenser by the following statement:—As the heat taken from the source is to the heat given up to the condenser, so is the temperature of the source to the temperature of the condenser. It is obvious that this mode of defining temperature necessitates an absolute zero, because less than no heat cannot be given to the condenser. Lord Kelvin and Mr. Joule found, by experiments on the change of temperature of gases when forced through porous plugs, that a comparison could be made between the thermodynamic scale and the ordinary gas thermometer scale. The results proved that when using air, nitrogen, or hydrogen gases, the thermodynamic scales and the gas thermometer scales were not sensibly different. Hence we arrive at the conclusion that there is an absolute zero of temperature, and that it is close to $-273°$ on the Centigrade scale, and also that the scale of temperature defined by the constant-volume nitrogen or hydrogen thermometer is closely in accordance with the absolute thermodynamic scale. When, therefore, we speak of absolute temperatures it is understood to mean temperatures reckoned on that scale on which the melting-point of ice is 273° and the boiling-point of water under normal pressure is 373°.

We can now specify more exactly the relation of heat and temperature. If a quantity of heat is imparted to a body not sufficient to change its phase or state from solid to liquid or liquid to gas, it will raise its temperature by an amount such that the rise in temperature in degrees is equal to the quotient of the heat given in calories by the mass of the body in grammes, and by a coefficient called the specific heat at that temperature, or, symbolically

$$T = \frac{H}{MS},$$

where T is rise in temperature, H is quantity of heat, M is mass, and S is specific heat. If heat can escape from the body by radiation, conduction, or convection, then the total heat imparted to it must supply the loss as well as the rise in temperature. If, therefore, we can prevent heat from escaping from a body, a very small rate of production of heat in it will, if continued for long, raise the temperature to a very high degree.

In general, when conducting metallurgical or other chemical operations, we require a mass of matter to attain a certain temperature, and that often as quickly as possible. We can best achieve this by insulating the body for heat as completely as possible, and creating the heat inside it electrically. There are, however, some paradoxes in connection with this matter. If, for instance, we pass an electric current through a wire and generate heat in it at a certain rate, the temperature will gradually rise until a point is reached at which the loss of heat by radiation and convection, which increases with the temperature, just balances the heat gain, and the temperature then remains stationary. If part of a platinum wire is closely covered with glass melted on to it, it might be supposed that this,

by keeping in the heat, would cause that covered part to rise to a higher temperature than the rest. As a matter of fact, as first noticed by Professor A. W. Porter, it keeps that part cooler. The reason is that the glass becomes a thermal conductor when hot, and as the covered portion offers a larger surface for the escape of heat than the bare part, the coated part never attains so high a temperature as the uncoated part.

As a rule, however, covering a conductor with asbestos, or other non-inflammable heat insulator, causes it to come to a higher final temperature when a given steady current is passed through it.

Assuming, however, that the body is brought to a high temperature and allowed to lose heat by radiation, an important question is the relation between the temperature and the energy sent out as radiant heat per square unit of surface. Professor J. Stefan suggested, in 1879, and Professor Boltzmann, in 1884, showed theoretically, that the relation between temperature and radiated energy is as follows:—The energy (E) radiated as heat from every square unit of surface of a black body is proportional to the fourth power of the absolute temperature of that surface, or

$$E = KT^4,$$

where K is some constant. As, however, the radiating body is always in some enclosure at a temperature T_0 the law is better specified by the formula

$$E = K\,(T^4 - T_0^4).$$

It will be noticed that the above law is specified for a "black body," and it is necessary to explain what this means. A perfectly black body is one which absorbs all rays falling upon it and reflects and transmits none. No actual surface is perfectly black at all angles of incidence, not even lampblack, which is the nearest approach. A perfectly black area may, however, be realised by making a small hole in a large hollow metal ball. If rays fall on the hole they enter and are scattered about by reflection in the interior, but few or none emerge again. Hence the area of the hole as viewed from outside is a black body. In consequence of the universal law of radiation that good absorbers are good radiators, it follows that a lampblack surface radiates at any temperature the maximum energy possible. For if there were any surface which could radiate more than a black surface, it would, *ipso facto*, absorb better, but that is impossible, because by hypothesis it absorbs all the rays which fall upon it. Hence the black body is the body which has the maximum radiation at a given temperature. Accordingly we can obtain a perfectly black radiator by making a small hole in a metal or other hollow sphere, and then heating this ball to the required temperature. The radiation which comes out of the hole will be black-body radiation. The material of which the ball is made is of no consequence. For the radiation which proceeds from the hole is not merely the radiation emitted from the interior parts visible through the hole, but is supplemented by radiation from all other portions reflected from those visible parts. Now, the reflecting power of an opaque body is the complement of its absorbing power, and therefore of its radiating power. Hence, even if the interior of the ball were coated with a white substance, the increased reflecting power would just compensate for the decreased radiating power, and the radiation escaping from the hole would be substantially the same as if the interior were coated with lampblack. Practically we can construct a radiator which is in effect a black body, by inserting into a furnace a metal or porcelain tube closed at the bottom (see Fig. 1). This tube

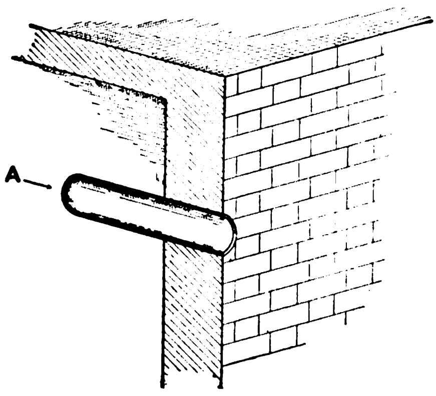

FIG. 1.—A CLOSED TUBE BUILT INTO A FURNACE TO FORM AN IDEAL "BLACK-BODY" RADIATOR.

becomes red-hot, and the radiation proceeding from the open end of the tube is substantially black-body radiation. The Stefan-Boltzmann law can thus be applied by means of instruments called radiation pyrometers—to be described presently—to the determination of furnace temperatures, and that of other radiant bodies, including even the sun. Another important law of radiation is that enunciated by Professor W. Wien in 1879, known as the Wien displacement law. If we expand the radiation from any hot body, by means of suitable diathermous prisms or a diffraction grating, into a spectrum, and measure by means of the bolometer the

energy contained in successive narrow slices of the spectrum, and represent these radiated energies

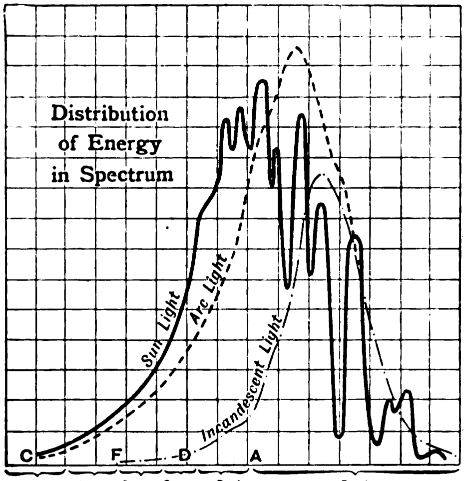

FIG. 2.—CURVES REPRESENTING BY THE HEIGHT OF THEIR ORDINATES THE ENERGY DISTRIBUTION IN THE SPECTRUM OF VARIOUS ILLUMINANTS.

as ordinates in terms of the corresponding mean wave length, we obtain a curve called an energy curve, which for most artificial sources of light has a maximum value, somewhere in the spectrum, mostly beyond the red or in the ultra-red part of the spectrum (see Fig. 2). Let the wave length corresponding to the

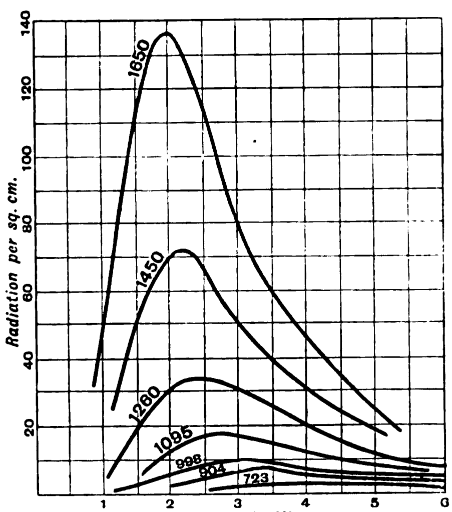

FIG. 3.—CURVES REPRESENTING THE RADIATION PER SQ. CM. FOR A "BLACK BODY" CORRESPONDING TO VARIOUS WAVE LENGTHS (MEASURED HORIZONTALLY) AND FOR VARIOUS ABSOLUTE TEMPERATURES AS MARKED ON THE CURVES.

portion of maximum energy be denoted by λ_m, and let the surface absolute temperature of the radiant body be T. Then Wien's law is, that the product $\lambda_m T$ is constant. Hence, in proportion as the absolute temperature rises, the wave length of the rays of maximum energy falls or is displaced towards the violet end of the spectrum.

The curves in Fig. 3—taken from a paper by Lummer and Pringsheim in the *Annalen der Physik und Chemie*, Vol. 63, p. 395, 1897—delineate these energy curves for a black body at various absolute temperatures marked on them. The abscissæ are wave lengths in microns (μ), or thousandths of a millimetre, and the ordinates are proportional to the intensity of the radiation.

In this case the product of $\lambda_m T$ is, on an average, equal to 2,940. Wien also showed that the energy radiated by a narrow slice of the spectrum at the point of maximum energy varied as the fifth power of the temperature of the radiant body, or $E_m \cdot T^{-5}$ is a constant quantity.

Wien's two laws, and also the Stefan-Boltzmann law, have received full experimental confirmation within certain limits. Wien's first law holds good even for bodies which are not black, but then the constant value of $\lambda_m T$ is less than that for a black body.

Wien has also shown how to obtain theoretically an expression for the energy E emitted per unit of surface by a black body at an absolute temperature T at various wave lengths λ. His result is as follows—

$$E = A\lambda^{-5} \epsilon^{-B/\lambda T},$$

where A and B are constants. The above expression is, in fact, the equation for the energy curve of the spectrum of the black body. Planck has modified Wien's formula into the form

$$E = A\lambda^{-5} \left(\epsilon^{B/\lambda T} - 1 \right)^{-1},$$

which is slightly more accurate, or agrees better with experimental results. It is obvious that the above expressions for E are functions of λ and T which have small values both when λ is very small and when it is very large, assuming T constant. Also it is easy to prove by differentiating the expression for E with regard to λ that it has a maximum value corresponding to a certain value of λ, and we can thus deduce both of Wien's laws, viz., that $\lambda_m T$ is constant and hence that the product $E_m T^{-5}$ is also constant, from the above expressions for E.

In Fig. 4 are shown a set of such radiation curves plotted by Dr. Drysdale from Wien's formula, giving the values A = 41400 and B = 14700 to the constants. The value of the constant in Stefan's law has also been experimentally determined. One of the latest measurements is by E. Bauer and M. Moulin (see *Journal de Physique*, 1910, Vol. XI., p. 468). They obtain the value $5 \cdot 3 \times 10^{-12}$, which is the factor by which the fourth power of the absolute temperature of the surface must be multiplied to give the radiation in watts

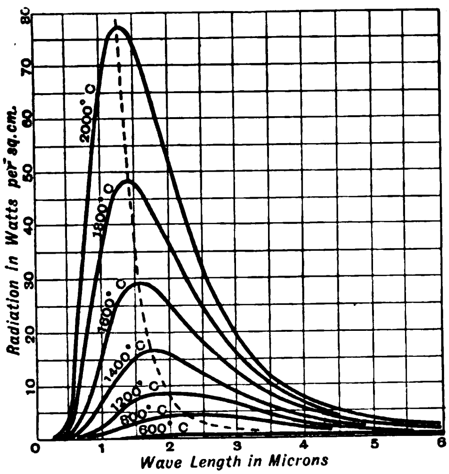

FIG. 4.—RADIATION CURVES PLOTTED BY DR. DRYSDALE FROM THE EQUATION $E = 41400\lambda^{-5}\epsilon^{-14700/\lambda T}$.

per square centimetre of surface. In any case, therefore, in which we can determine the radiation in watts per square centimetre of a radiating body, we can determine the surface absolute temperature, provided the radiant body is substantially a black body. For instance, in the case of a 14 c.p. carbon-filament glow-lamp radiating 50 watts, the carbon surface was found to be nearly one square centimetre. Hence, using the above constant in Stefan's law, the absolute temperature of the filament should be

$$T = \sqrt[4]{\frac{50 \times 10^{12}}{5 \cdot 3}} = 1760^\circ \text{ abs.} = 1487^\circ \text{ C.},$$

and this is known to be not far from the temperature of a carbon filament working at 3·5 to 4 watts per c.p.

Determinations of the solar radiation by various means have shown that the sun's photosphere radiates at the rate of 10,000 watts per square centimetre. Hence the absolute temperature should be

$$T = \sqrt[4]{\frac{10000 \times 10^{12}}{5 \cdot 3}} = \frac{10000}{\sqrt[4]{5 \cdot 3}} = 6660^\circ \text{ abs.}$$
$$= 6400^\circ \text{ C.}$$

Numerous measurements have shown that the solar photosphere on its outer portions has a temperature between 6,000° C. and 7,000° C.

Again, observations on the area of the crater on the positive carbon of an electric arc, combined with a measurement of the power expended on it, show that for a 10-ampere arc the radiation from the crater is at the rate of 25 or 30 watts per square millimetre or 2,500 to 3,000 watts per square centimetre. Hence the absolute temperature of the arc crater should be

$$\sqrt[4]{\frac{2500 \times 10^{12}}{5 \cdot 3}} = 4600^\circ \text{ abs.}$$

This is equivalent to 4,327° C. This value is rather higher than that obtained experimentally, but the difficulty of measuring the area of the arc crater accounts fully for the difference. Nevertheless, the temperature is of the right order. In the same manner Wien's first law can be employed to determine the temperature of an approximately black body whenever the wave length of the ray of maximum energy can be determined. For instance, Lummer and Pringsheim determined in this manner values for the temperature of various radiators as below

Source of Radiation.	Wave lengths in microns of ray of maximum energy emitted, $= \lambda_m$.	Absolute Temperature deduced by Wien's formula $T = 2940/\lambda_m$.
The Sun . .	$0 \cdot 55 \times 10^{-3}$ mm.	5300° abs.
Electric Arc .	0·7 " "	4200° "

Candle . . .	1·5 " "	1960° "
Argand Gas Burner . .	1·55 " "	1900° "

The value of λ_m for the sun is uncorrected for atmospheric absorption, which is known to reduce the apparent temperature of the sun. This absorption cuts off at least 20 per cent. of the solar radiation. Hence we must increase the value (5,300°) by one-fifth and we have 6,400° abs., a value quite close to that obtained by the application of Stefan's law.

It is interesting to note that the wave length of light for which the eye is most sensitive is in the yellow-green, which is in the neighbourhood

of that wave length $0 \cdot 55\mu$, which has the maximum energy.

It should be added that in making this measurement of the wave length of solar light conveying the maximum energy, the diffraction or normal spectrum must be employed and the energy estimated by the bolometer.

We can now pass on to consider the more accurate measurement of temperature by electrical methods, as a preliminary to discussing the technical applications of heat produced electrically.

There are three methods of temperature measurement based on electrical phenomena which have been brought to a state of great perfection, and provide the means of conducting and controlling operations in the arts and manufactures far exceeding in accuracy any of the older methods of thermometry depending upon the expansion of solids, liquids, or gases. These methods of temperature measurement are as follows:—(1) By electrical resistance thermometers; (2) by thermo-electric pyrometers; (3) by radiation or optical pyrometers.

The first method is based on the well-known fact that the electrical resistance of pure metals increases with the temperature. In conjunction with Sir James Dewar, the writer made an extensive investigation of the variations of resistance of extremely pure metals between temperatures of $+200°$ C. and $-200°$ C., and depicted the result in a chart. It was found that these lines slope downwards at various angles, but so as to indicate that in the neighbourhood of the absolute zero the electrical resistance of pure metals would be vanishingly small. As far back as 1871 Sir W. Siemens had proposed to use the variation of resistance of pure platinum as a means of temperature measurements, but in consequence of variations in the resistance, caused by the manner in which he supported the wire by winding it on a porcelain rod, the first attempts were not very encouraging.

It was not until 1887 that the careful researches of Callendar re-established the value of this method of temperature measurement. Callendar employed a fine wire of pure annealed platinum so supported by being wound loosely on a mica frame that it was not in contact with clay at a high temperature. Platinum placed in contact with clay or porcelain at very high temperatures becomes contaminated with impurities which change its electrical qualities. This fine wire is welded to two other thicker platinum wire *leads*, and a pair of the same thick wires of equal length, but joined directly together at the bottom, are used as "compensating leads," and placed in contiguity to the actual leads. If, therefore, we measure on a Wheatstone's bridge

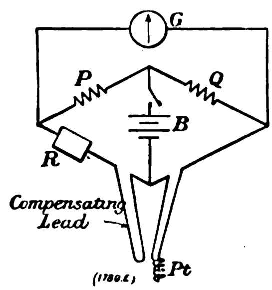

FIG. 5.—WHEATSTONE'S BRIDGE ARRANGEMENT OF CIRCUITS FOR MEASURING PLATINUM THERMOMETER RESISTANCE.

(see Fig. 5), or by a differential galvanometer, or in any other way, the difference of the resistance of these two circuits, this difference is equal to the resistance of the fine platinum wire. This wire may then be placed in any region the temperature of which it is desired to know. If R_t is the resistance of the wire at $t°$ C. and R^0 is its resistance at 0° C., then it is found that

$$\frac{R_t}{R_0} = 1 + \alpha t + \beta t^2,$$

where α and β are called temperature coefficients. The above is the equation for a parabola, and hence the resistance is said to be a parabolic function of the temperature. The coefficient β is generally small, and for platinum α is a quantity near $0 \cdot 00365$. Between 0° and 100° the resistance curve is nearly a straight line. Let R be the resistance of the wire measured at any temperature $t°$ C. Callendar introduced a new way of measuring temperature according to a scale called the *platinum temperature* (*pt*) *scale*, as follows:—The increment of resistance of platinum is proportional to the increment of platinum temperature. Hence, if R, R_0 and R_{100} are resistances at (*pt*) 0° C. and 100° C. respectively, we have

$$pt = \frac{R - R_0}{R_{100} - R_0} .100.$$

Callendar showed that the relation of the platinum temperature to the air thermometer temperature (t) could be expressed by the formula

$$t - pt = \delta \left(\frac{t}{100} - 1\right)\left(\frac{t}{100}\right).$$

The quantity δ is called the *principal constant* of the thermometer, and is related to the temperature coefficients α and β as follows

$$\alpha = c\left(1 + \frac{\delta}{100}\right), \ \beta = - c\delta/10000.$$

Hence, if we measure the platinum temperature by the resistance of the wire, we can at once convert the reading into air-thermometer temperature.

platinum wire at 0° C. This is easily done by a rheostat A and switch S, as shown in Fig. 8.

Many instrument-makers now furnish direct-reading platinum resistance thermometers, made

FIG. 6.—PLATINUM RESISTANCE THERMOMETER IN A QUARTZ TUBE. (Messrs. J. J. Griffin & Sons.)

on one or other plan, and in some cases the platinum wire is protected by insertion into a steel tube when it is to be used to determine furnace temperatures. In all cases the compensating leads must be run down the same tube as the leads connected by the platinum thermometer wire, so that all parts of them may be at the same temperature and vary in the same way as the actual leads. This obviates any correction for lead resistance. The resistance of the

Another formula for doing this directly is that due to Mr. J. Hamilton Dickson, who showed that if R is the resistance of a platinum wire in ohms at t° C., then

$$(R+a)^2=p\ (t+b),$$

where a and b are constants.

In carrying into effect practically this method of measuring temperature the platinum wire has to be supported and protected so that it can be placed in any region of temperature between absolute zero and 1,200° C. and at the same time take up quickly the temperature of the region. This may be done by winding the platinum wire on a quartz rod, over which is placed a quartz tube, and the two are melted together so that the turns of platinum wire are embedded, kept in place, and protected by an infusible covering not easily acted on by heat or chemical agents. Such a platinum resistance thermometer is here exhibited, kindly lent me by Messrs. J. J. Griffin & Sons (see Fig. 6). The resistance wire and its leads and the compensating leads are then connected into a Wheatstone's bridge, as shown in Fig. 5. We may then balance the bridge in the ordinary way by adjusting the resistance of the arms so that the galvanometer G shows no current in the bridge, and determine the resistance R of the thermometer T by the ordinary bridge formula; and hence the platinum temperature pt by the formula already given. On the other hand, the increase in resistance of the thermometer wire when heated may be allowed to create a current in the galvanometer circuit, and the galvanometer scale may be calibrated so as to indicate by the galvanometer needle deflection Centigrade temperature of the wire directly, as in the instrument shown in Fig. 7, which is supplied by Messrs. Griffin & Sons.

In this case we have to provide some means for regulating the battery current so that the galvanometer always reads zero when in place of the platinum thermometer we substitute a constant resistance R_4 equal to that of the

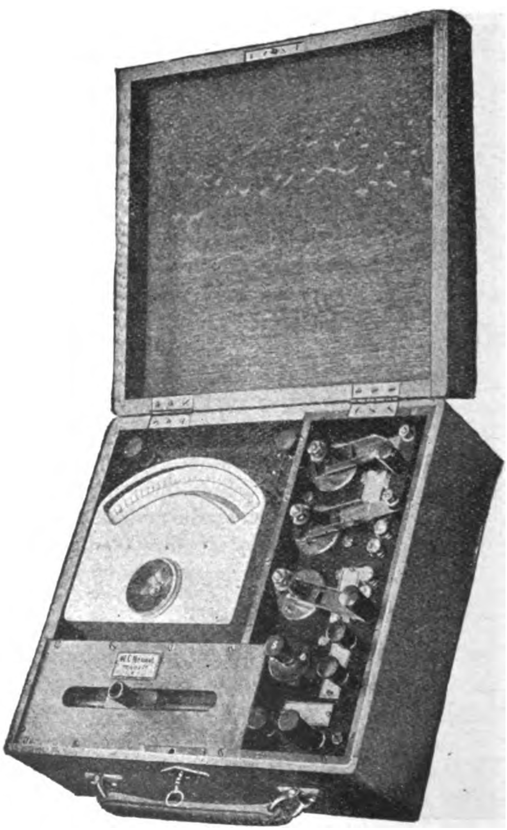

FIG. 7.—DIRECT-READING COMBINED BRIDGE AND GALVANOMETER FOR TAKING PLATINUM TEMPERATURES WITH THE QUARTZ THERMOMETER. (Messrs. J. J. Griffin & Sons.)

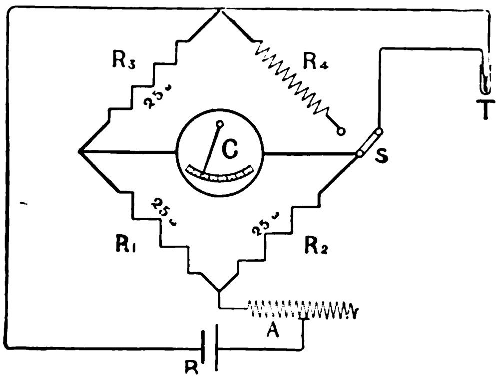

FIG. 8.—SCHEME OF CONNECTIONS OF THE DIRECT-READING WHEATSTONE'S BRIDGE AND PLATINUM THERMOMETER SHOWN IN FIG. 7.

platinum thermometer wire may be five or ten ohms, and a resistance is provided exactly equal to the resistance of that wire at 0° C.

In the direct-reading forms of bridge, where the deflection of the galvanometer gives the reading at once, the operation of taking a temperature with the platinum resistance thermometer is just as speedy as taking it with a mercurial thermometer, but is a great deal more accurate. Moreover, the actual thermometer wire need not be near the bridge, and several platinum thermometers can be adjusted to be read by one bridge with the aid of a switch. Hence, the temperature in distant parts of a building, in chimneys, flues, inaccessible parts of steam-boilers, vats or heaters, can be taken in an office or laboratory without moving the reading instrument (see Fig. 9). In these cases the platinum thermometer wire should have a rather high resistance, and the connecting leads resistances not exceeding one ohm. Moreover, by recording instruments it is quite easy to obtain a curve on paper showing the continuous variation of the temperature of any region far or near.

There are, therefore, several different methods by which the temperature of a region can be ascertained by means of the platinum thermometer. For scientific purposes, where speed is not an object, we may determine the resistance of the platinum wire by the ordinary Wheatstone's bridge measurements made with great care. The particular thermometer used must then have its principal constant δ determined by measuring its resistance at three fixed temperatures. The most convenient are the melting-point of ice (0° C.), the temperature of the steam of water boiling under 760 mm. pressure (100° C.), and the boiling-point of sulphur under the same pressure (444°·55). Having obtained the value of δ, which varies slightly from wire to wire, we can obtain the Centigrade temperature ($t°$) corresponding to any platinum resistance (pt) from the formula

$$t - pt = \delta\left[\left(\frac{t}{100}\right)^2 - \frac{t}{100}\right].$$

The value of δ for pure platinum is nearly 1·5.

Tables have been published (see "Technical Thermometry," by the Cambridge Scientific Instrument Company, Ltd.) giving the value of the air thermometer temperature for various platinum temperatures from 0° to 1,100° C.,

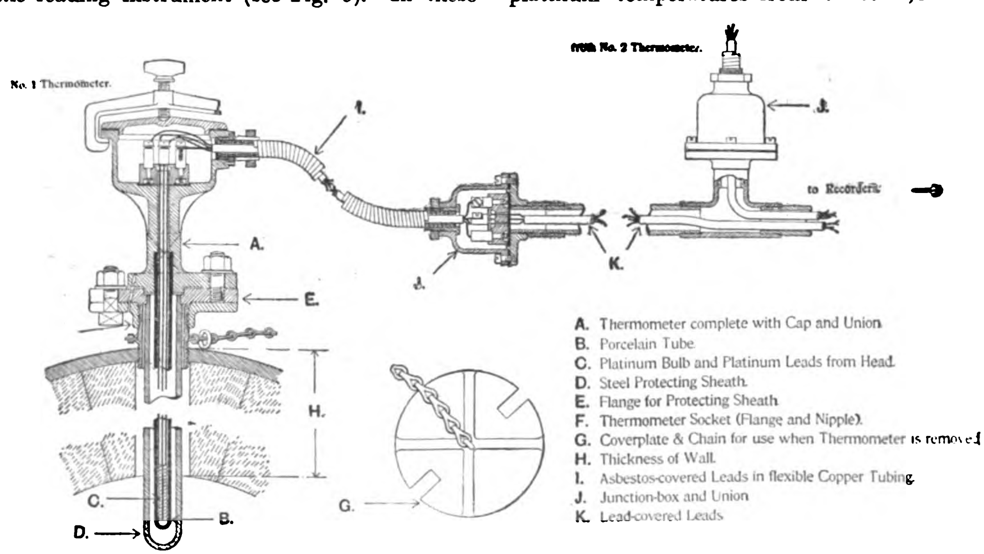

FIG. 9.—PLATINUM RESISTANCE THERMOMETER PLACED IN A HOT-AIR MAIN TO RECORD TEMPERATURES BY WHIPPLE OR CALLENDAR RECORDER.

which greatly facilitate the use of the resistance thermometer. The two scales agree at 0° C. and 100° C, but at 1,000° C. the corresponding platinum temperature is 865° *pt*. Thus above 100° C. the platinum temperature is always numerically less than the air scale temperature.

For industrial purposes the adjustment of the bridge resistance may be made to show directly on some scale the temperature at the instant when the galvanometer needle is at zero and the bridge balanced. This is done in the Whipple Temperature Indicator, as constructed by the Cambridge Scientific Instrument Company (see Fig. 10), where the battery, galvanometer, and bridge are all contained in one box and the resistance thermometer placed at a distance in some locality where the temperature has to be determined, but connected with the bridge by suitable leads. Or else a Callendar recorder, by the same instrument makers, may be used (see Fig. 11). This is an arrangement in which the deflection, one way or the other, of the coil of a movable-coil galvanometer, which is placed in the bridge circuit, closes another circuit and causes a motor to move a pen along a sheet of paper in such manner that when the temperature rises, the pen moves one way, and when it falls, the pen moves the other way. The pen therefore traces a continuous record on the paper, showing the variations of resistance of the platinum wire corresponding to the variation in the temperature of the locality in which it is placed (see Fig. 12).

In place of a Wheatstone's bridge, some type of ohmmeter may be used to measure the resistance of the platinum wire at various temperatures. In the Harris direct-reading resistance thermometer a differential ohmmeter is employed which measures and shows by the deflection of a needle on a scale the difference in the resistance of a platinum resistance thermometer and that of the compensating leads. This instrument is made by Mr. R. W. Paul, and is certainly one of the most convenient forms of direct-reading thermometers.

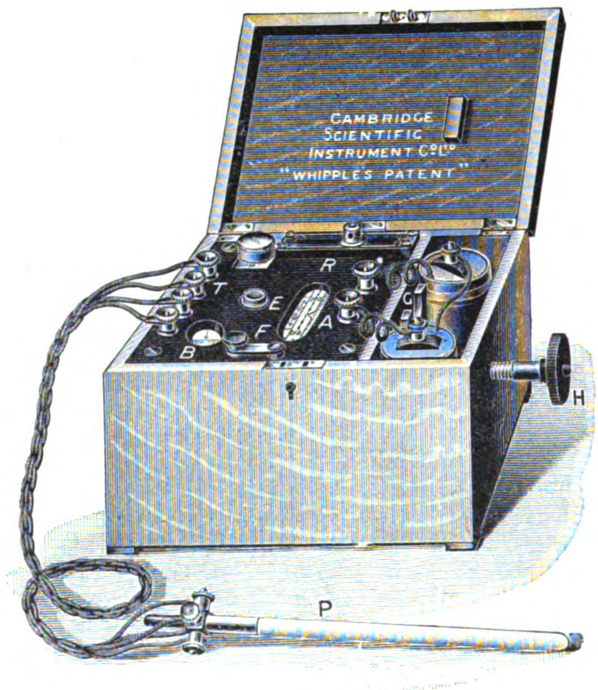

FIG. 10.—WHIPPLE TEMPERATURE INDICATOR AND PLATINUM RESISTANCE THERMOMETER P, AS MADE BY THE CAMBRIDGE SCIENTIFIC INSTRUMENT COMPANY.

A few important industries in which such platinum thermometry is now employed to record or control temperatures are as follows:—In hardening steel tools a variation of even a few degrees in the temperature to which the metal is raised makes a difference in the result. A great authority, Mr. Brayshaw, says that a variation of 5° C. makes all the difference between good and bad hardening. In brick and

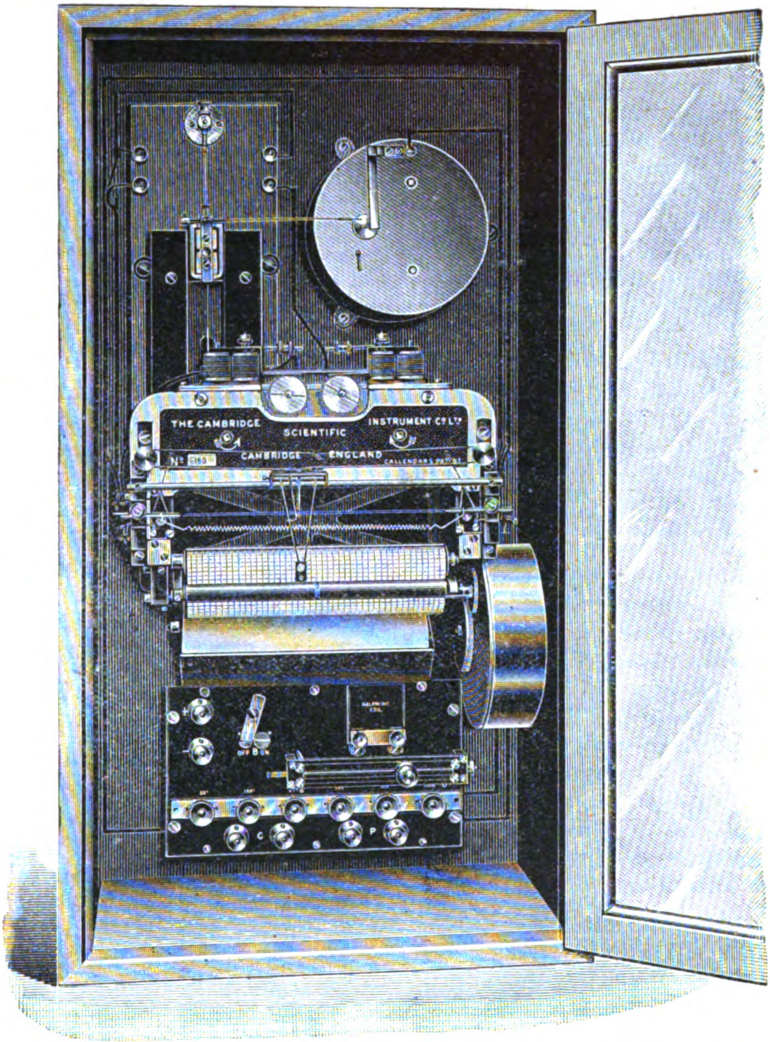

FIG. 11.—CALLENDAR RECORDER FOR RECORDING GRAPHICALLY VARIATION IN TEMPERATURE.

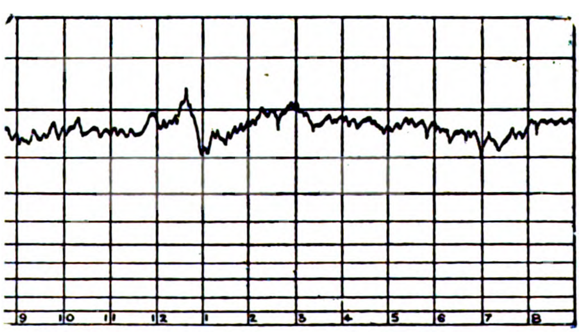

FIG 12.—A GRAPHIC RECORD OF TEMPERATURE VARIATION AS MADE BY A CALLENDAR RECORDER.

porcelain kilns a knowledge of the temperature is most important. In breweries, cold storage, blast furnaces, superheaters, steel annealing, jam boiling, and innumerable other arts, the success of the operation depends entirely on the temperature not falling below or rising above certain limits. A platinum resistance thermometer provides the simplest and most accurate means for determining and recording the temperature from moment to moment, even when the measurement has to be made at a point not very near the place at which it is recorded.

A second method of temperature measurement is based on the facts of thermo-electricity. If a circuit is formed of two wires of different materials, and if the junctions are kept at different temperatures, there is in general an electromotive force in the circuit called a thermo-electromotive force. For every pair of

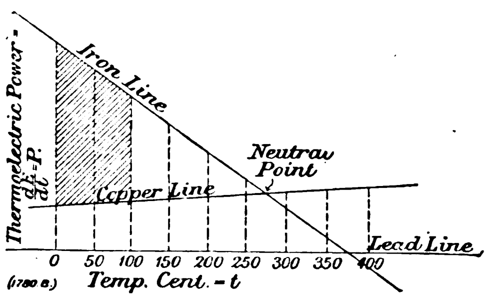

FIG. 13.—THERMO-ELECTRIC LINES OF IRON AND COPPER IN A THERMO-ELECTRIC DIAGRAM.

metals there is, however, a certain temperature called the neutral temperature, at which the metals are thermo-electrically identical, so that if the temperature of one junction is as far above the neutral temperature as the other is below it, there is no current in the circuit.

Speaking generally, however, there is one source of electromotive force at the junction of two metals which is a function of the temperature, and is called the Peltier effect. Hence, generally in a thermo-couple the E.M.F. is partly due to unequal Peltier effects at the two junctions. But there is also a second source of E.M.F. called the Thomson effect, which is due to the fact that portions of the same metal at different temperatures are thermo-electrically different. Hence, when there is a gradient of temperature down a metal wire, there is also a source of electromotive force in it.

The facts of thermo-electricity are best represented by a thermo-electric diagram having drawn on it the so-called thermo-electric lines. For each metal we can draw on it a line approximately straight such that if abscissæ represent temperature the ordinates represent thermo-electric power, $P = d\,E/dt$ (see Fig. 13). The line representing *lead* is taken horizontal and as the datum line. If a couple be made of the given metal and lead, and if the junctions are kept at temperatures t and $t + dt$, where dt is a small difference, then the thermo-electric power of the given metal at the temperature t is defined to be the rate at which the E.M.F. in the metal-lead couple circuit is changing at that temperature. Hence

$$P = \frac{dE}{dt} \text{ or } E = \int P\,dt.$$

If two ordinates are drawn corresponding to two temperatures, T_1 and T_2, then the area included between these ordinates and the thermo-electric line of the metal and the base line of lead represents to scale the E.M.F. in the circuit. If, therefore, we draw the thermo-electric lines of two metals, A and B, and form a couple of them with junctions at temperatures T_1 and T_2, then the area included between the two thermo-electric lines and the two ordinates represents to scale the E.M.F. in that circuit. For our present purpose it will not be necessary to enter into a discussion of the facts of thermo-electricity further than to say that with the exception of iron and bismuth the thermo-electric lines of most metals are nearly straight lines, and this indicates that the thermo-electromotive force produced by a moderate difference of temperature of the junctions is a parabolic function of that difference, or may be represented by such a function as

$$E = A + B\,(T_1 - T_2) + C\,(T_1 - T_2)^2,$$

where A, B, and C are constants for that pair of metals. It has been found, however, that a formula given by Holman in the form

$$\log E = M \log T + N,$$

fits the facts better for a larger range of temperature, M and N being constants for any chosen pair of metals and T being the temperature of the hot junction, the other being kept constant. This formula has the advantage of being linear; that means it is the equation to a straight line when plotted in terms of log E and log T, and hence can more easily be extrapolated.

The constants can, of course, be determined by measurements of the E.M.F. made with the hot junction at known temperatures.

Accordingly, if we have such a couple of metals selected so that a neutral point does not lie within the range of temperature over which it will be used, and if we calibrate the couple

by measuring the E.M.F. at three fixed temperatures, say 0° C., 100° C., and some much higher temperature, such as the freezing-point of lead, then we can use it for the determination of intermediate or somewhat higher temperatures. The method now always adopted is to read the E.M.F. with a high-resistance voltmeter

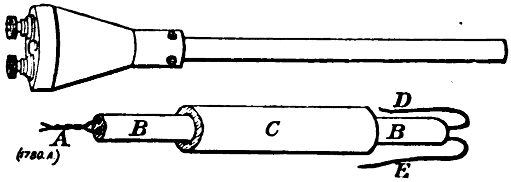

FIG. 14.—DIAGRAM SHOWING THE MODE OF INSULATING THE WIRES OF A THERMO-COUPLE.

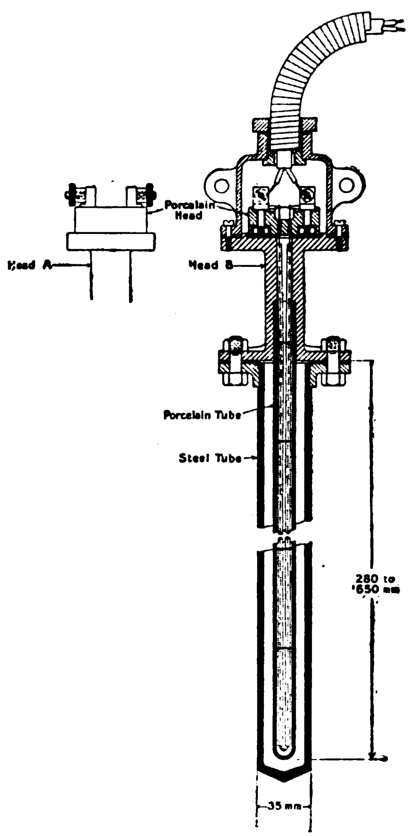

FIG. 15.—THERMO-COUPLE ENCLOSED IN A STEEL TUBE.
(The Cambridge Scientific Instrument Company.)

which has its scale marked directly to read temperature.

The metals chosen for the couple are in the form of wires of copper and nickel, or copper and constantan (a copper-nickel alloy) for moderate temperatures up to 1,000° F., and a couple of platinum with platinum alloyed with 10 per cent. of either iridium or rhodium for high temperatures.

Wires of the two metals are run down separate holes in porcelain or quartz tubes to insulate them, the ends are welded together at the bottom, and these tubes are then enclosed in a steel tube for safety (see Figs. 14 and 15). The wires are made long enough to connect to a high-resistance volt-meter, and these junctions are kept well away from the source of heat. If the lower closed end of the steel tube, where the thermo-junction lies, is placed in a furnace, it soon takes the surrounding temperature, and an E.M.F. is produced which causes a deflection of the volt-meter, generally a movable-coil instrument, and the temperature is read off directly in the scale. It is necessary that the cold junction should be kept at the same temperature, or if it alters that a correction should be applied. Messrs. Crompton in their pyrometer do this by providing several scales applicable respectively to the atmospheric temperatures marked on them.

These scales are graduated by placing the hot junction in regions of known temperature obtained from the melting or rather the solidifying temperatures of various metals. Thus, in addition to 0° C., and 100° C., we can use the freezing-point of molten lead = 327° C., the freezing-point of silver = 955° C., and that of gold = 1,064° C., which are known pretty accurately.

The commercial thermo-electric pyrometer in this form is a handy instrument, but when the couple is formed of base metals or alloys, such as copper-constantan, copper-nickel, or copper-steel, the couples need recalibrating at intervals, and are only available for temperatures up to about 800° C. for higher temperatures, the platinum and platinum-iridium (Pt + 10 per cent. Ir.) is used.

Such thermo-couples may be made self-recording by photographic devices. Thus, in the Roberts-Austen-Pitkin pyrometer the volt-meter is replaced by a high-resistance movable-coil mirror galvanometer, and a ray of light reflected from the mirror falls upon a slowly-revolving drum covered with photographic paper, which is driven round by clockwork. The variations in the deflections of the galvanometer are made to record themselves by a line marked on the paper; the ordinates of this line denote temperatures, and can, by proper calibrations, be interpreted into Centigrade temperatures (see Fig. 16).

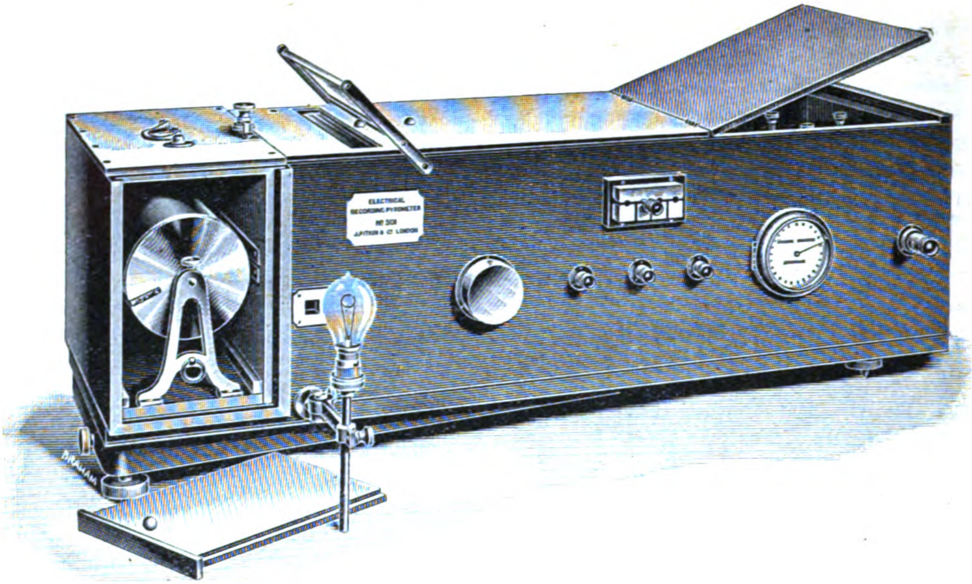

FIG. 16.—ROBERTS-AUSTEN PHOTOGRAPHIC RECORDING PYROMETER, AS MADE BY MESSRS. PITKIN AND WHITE.

The Cambridge Scientific Instrument Company have constructed an ingenious instrument called a thread-recorder, for the automatic record of thermo-electric pyrometers and other instruments (see Figs. 17 and 18). In this instrument a movable-coil galvanometer has a long light needle of aluminium attached to its coil, and this moves to and fro over a drum covered with paper. Between the needle and paper surface is an inky thread, and the needle swings just clear of the thread. At short intervals, by means of clockwork, a bar is brought down on the needle of the galvanometer, catching it in any position, and presses it against the inky thread and on to the paper. The exact position of the needle is, therefore, recorded by a dot on the drum, and the series of dots marks out the various positions of the galvanometer needle, and therefore records the temperature if a thermo-electric junction is connected to it.

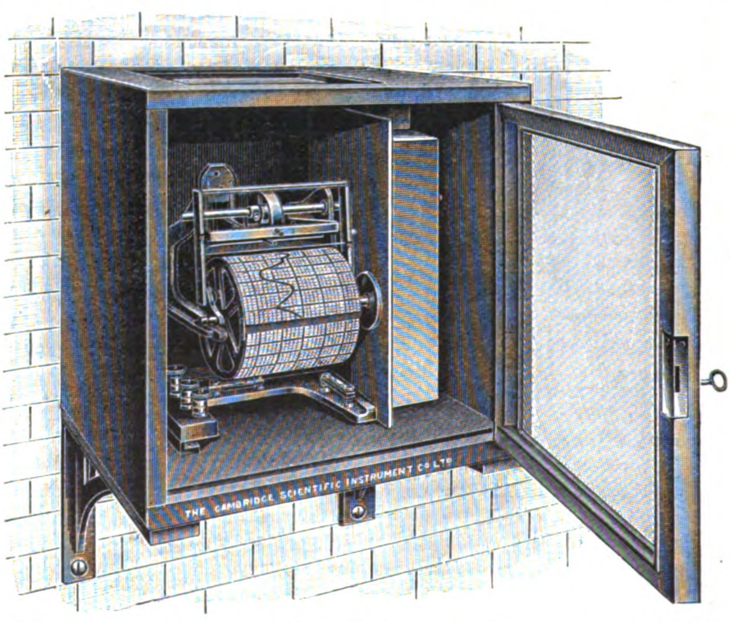

FIG. 17—THE THREAD-RECORDER OF THE CAMBRIDGE SCIENTIFIC INSTRUMENT COMPANY.

For accurate work, it is essential that the cold junction should be kept at a constant temperature, or else introduce an opposing E.M.F. into the circuit, which neutralises that due to the cold junction. An ingenious method of this latter kind has been devised by Messrs. Stroude and Josephs. It consists in introducing into the thermo-junction circuit an electromotive

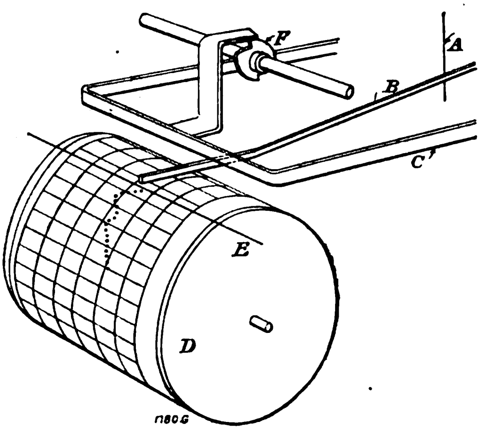

FIG. 18.—DIAGRAM SHOWING THE PRINCIPLE OF THE THREAD-RECORDER.

force which is created by any variation of the cold junction from a standard temperature, say, 5° C. A Wheatstone's bridge arrangement is formed of pairs of conductors of large and small temperature coefficients used as the opposite arms of the bridge. Hence, any variation of temperature creates an E.M.F. in the bridge circuit. The thermo-junction is inserted in this bridge circuit, and the bridge arms are placed in the same region as the cold junction and adjusted so that variation of temperature keeps a constant E.M.F. in the cold junction.

Lastly, we have to consider means for measuring higher temperatures than those which can be measured with a thermo-couple about (1,200° C.), and also cases in which the hot body cannot be approached.

For this purpose advantage is taken of the Stefan-Boltzmann law that the temperature of a radiating body varies as the fourth root of the radiation per second per unit of area.

If we form an image of a distant hot body by means of a concave silver metallic mirror, the intrinsic temperature of this image does not depend upon the distance of the object. For the total heat collected varies inversely as the square of the distance, and also the size of the image varies inversely as the square of the distance, so that the heat thrown per second upon a square unit of area of the image is independent of the distance.

If, then, we place in this focus of the mirror a thermo-junction which is more than covered by the optical image of the hot body, the temperature to which this junction will be raised will depend upon the temperature of that object but not upon its distance. If, then, the thermo-couple is connected to a galvanometer we can calibrate the scale of the galvanometer by exposing the junction to the radiation from various baths of solidifying metals which are at known temperatures.

Professor Féry has constructed on these principles a radiation pyrometer which, as made by the Cambridge Scientific Instrument Company, serves admirably to determine furnace temperature, and that of steel in crucibles at the moment of pouring, Bessemer converters, etc.

The instrument is like a short Newtonian telescope, and has a concave silver mirror at the closed end (see Fig. 19). This forms an image

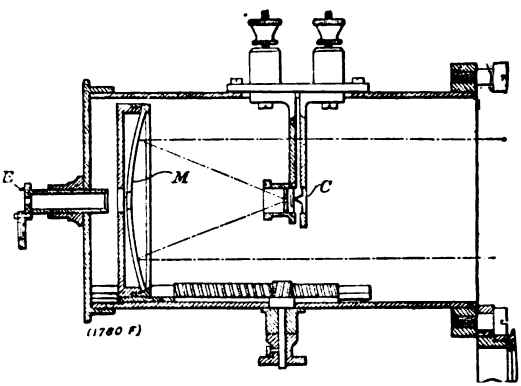

FIG. 19.—SECTION OF THE FÉRY RADIATION THERMO-ELECTRIC PYROMETER.

of the distant radiator at its focus, in which is placed a copper constantan thermo-junction in the form of a cross. This thermo-junction is protected by a small circular screen from the direct access of rays from the hot body. It is essential that the image of the hot body should rather more than cover this screen. To observe this the mirror is perforated with a hole and a suitable eye-piece placed in that aperture. The thermo-couple is connected to a single-pivot movable-coil sensitive galvanometer, which can be calibrated so as to read temperatures directly by exposing the instrument to the radiation from baths of molten metal just solidifying at known temperatures.

To determine a furnace temperature, an iron, fire-clay or porcelain tube closed at one end, has the closed end inserted into the furnace. The

radiation pyrometer is then adjusted so as to look down the tube and gather rays radiated from the closed end (see Fig. 20). This is practically black-body radiation, which follows Stefan's law, and the reading of the galvanometer gives us, therefore, the black-body temperature. If the radiating substance is one like carbon, steel, iron, copper, or lead, which is black or forms a black or dark-coloured object, we can take the temperature observed as the true temperature of the body.

If, however, the radiating body was a sheet of platinum in a state of incandescence, the real temperature of the body would be higher than that read on the galvanometer scale, because it is a poorer radiator at a given temperature than a black body.

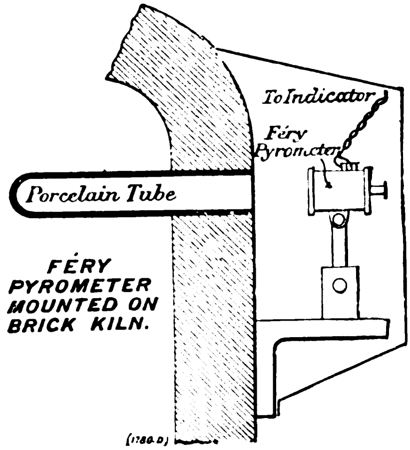

FIG. 20.—MODE OF USING THE FÉRY RADIATION PYROMETER.

By means of a thread-recorder galvanometer, as above described, a continuous record can be obtained of furnace temperatures far above the melting-point of steel. The applications of this radiation pyrometer in the Arts are innumerable, and enable us to ascertain and record the temperature of inaccessible places over a range between 600° C. and 2,000° C. with considerable accuracy.

In concluding this lecture it may be interesting to inquire what explanation modern electrical theory can furnish of the laws to which our attention has been directed. The theory of electricity which now holds the field with a considerable body of evidence in its favour is the electronic theory, which is based on the evidence that the agency we call electricity has an atomic character or structure. The atom of negative electricity is the *electron*. The electron is supposed to be a spherical structure in the æther, which is the focus of a number of converging lines of twist in the æther, and it can therefore be displaced without resistance through the stationary æther. The radius of an electron is, approximately, 10^{-13} centimetres, which is one-hundred-thousandth part of the average size of an atom. It represents a negative charge of electricity approximately equal to 3×10^{-10} of an electrostatic unit, or 10^{-20} of an electro-magnetic unit; it has a mass equal to 10^{-27} of a grain. In other words, one billion billion electrons weigh a milligramme, and 3,000 million carry an electric charge equal to one electrostatic unit.

The ratio of charge to mass, charge reckoned in electro-magnetic units, is 10^{-7}, whereas that of a hydrogen atom is 10^{-4}. The structure of the correlative positive electron is not so completely ascertained, but its diameter appears to be about 100,000 times greater than that of the negative electron, and its mass comparable with that of a hydrogen or helium atom.

Chemical atoms are complex structures of positive and negative electrons, from which, owing to rotatory or vibratory motions of the negative electrons, one or two of the negative electrons may be cast out.

Hence a piece of metal, such as a copper wire, must be thought of as a sponge-like structure consisting of complex arrangements of electrons forming the chemical atoms, each cubic centimetre containing about an equal number of free or detached negative electrons moving hither and thither in the atomic interspaces or jumping from atom to atom, with a speed on an average of sixty miles a second. The electronic theory shows that the sensible temperature of the metal is due to and measured by the mean kinetic energy of the free electrons alone, and that the conduction both of heat and electricity is also effected by the free electrons.

As regards flow of heat, if the electrons at one point have greater mean kinetic energy than at another, this energy density is gradually unified by the collisions of electrons with atoms and with each other, and this process constitutes the diffusion or conduction of heat. As regards electricity, the operation of an electromotive force applied to a conductor is to make an interior electric field, and this causes a movement of electrons in that direction which is superposed on their indiscriminate motion.

What we call the current in the metal at any point is the algebraic sum of the total number of free electrons passing through unit of area in the metal, and is measured by the product

of the mean velocity, the electronic charge, and the algebraic sum of the electrons so passing.

The heat produced in the conductor varies as the increase in the average kinetic energy of the electrons, and this varies as the increase in the mean-square velocity. Hence it follows that the heat produced by the current, which is the increase in the mean unidirectional kinetic energy produced by the electronic drift, must be proportional to the square of the mean electronic velocity, that is to the square of the current, and this is the statement of Joule's law. There is evidence that the energy of atomic motion, that is, of the atoms or complexes of chemical atoms, forms no sensible portion of the whole kinetic energy, and hence we may deduce Joule's law directly from the increase in electronic energy resulting from an applied electric force.

Starting from the assumptions that metallic conduction is effected by the movements of free electrons in the metal, and that these obey the laws of gas molecules confined in a vessel and have their velocities distributed in accordance with Maxwell's law, we can deduce Ohm's law, provided that the electric force applied to move the electron is not sufficient to cause a sensible change in the velocity of the electron between two collisions. According to Sir J. J. Thomson, the mean free path of an electron is about 5×10^{-7} centimetres, except in bismuth, where it is 10^{-4} centimetres. The mean free path of a gas molecule at ordinary temperature and pressure is 10^{-5} centimetres. In one cubic centimetre of copper there are about 10^{-23} atoms and about $1 \cdot 5 \times 10^{-23}$ free electrons. The mean kinetic energy of the free electron is the same as that of a free molecule of hydrogen at the same temperature.

Now, this theory is found to give a very accurate prediction and explanation of the known fact that the ratio of the electric to thermal conductivity in all metals is nearly the same and varies as the absolute temperature. We have then to explain how it is that rise of temperature in a pure metal reduces the electric conductivity. The current or electron drift produced by a given electric force or electromotive force per centimetre is proportional to that force and also to the time interval between two collisions of the electrons. The greater the speed of the electron, that is, the higher the temperature, the less therefore will be the electronic drift for a given electric force, and that implies that the conductivity or ratio of drift to force is reduced by rise of temperature.

Lastly, we may say that this theory of metallic conduction which ascribes all the phenomena to the operations of the free electrons has been able to give a good account of the laws of radiation enunciated by Stefan, Boltzmann, Wien, and Planck. The Stefan-Boltzmann law can be deduced theoretically by the application of Carnot's principle to the known fact that radiation exercises a pressure on black bodies on which it falls, and the laws of Wien have been deduced theoretically by Jeans from the electronic theory.

The results which are pretty generally accepted at the present time in reference to this subject may be briefly summarised in about twenty short statements as follows :—

1. According to the electronic theory, electricity has an atomic structure. The atoms of negative electricity are called electrons or negative corpuscles. They have each a mass of about $\frac{1}{1700}$ of that of an atom of hydrogen, and a diameter of about one billionth (10^{-12}) of a millimetre. This diameter is therefore about $\frac{1}{100000}$ part of the diameter of an hydrogen atom, or in the ratio of a pin's head to the dome of St. Paul's.

2. The nature of the atoms of positive electricity are not yet so completely determined, but they are much larger and heavier than negative electrons.

3. Chemical atoms or material atoms are structures composed of electrons, positive and negative, and from any chemical atom one or more negative electrons can escape or become free.

4. Conductors such as metals must be regarded as composed of chemical atoms, which are collocations of electrons in stable orbital motion, and a certain proportion of interspersed free electrons moving between the atoms, about equal in number to the atoms.

5. The electrons which are free must be regarded as jumping from atom to atom or colliding with them and as moving in all directions in the interatomic spaces with varying velocities distributed according to the same law as the velocities of gas molecules.

6. The mean kinetic energy of a free electron is the same as that of a free molecule of hydrogen at the same temperature.

7. The electrons have therefore a certain mean free path, and the laws of the kinetic theory of gases apply to them.

8. In 1 mm. cube of copper there are about 10^{20}, or 100 million billion copper atoms, and about 150 million billion free electrons ($= 150 \times 10^{18}$) moving with an average velocity of *sixty miles per second.*

9. The temperature of the conductor is determined solely by the mean kinetic energy of the free electrons, and in no sensible degree by the energy of motion of the chemical atoms or molecules.

10. Both conduction of heat and conduction of electricity are effected by the agency of the free electrons.

11. If one part of a conductor is at a higher temperature than another, then at the place of high temperature the free electrons have the greatest kinetic energy; but this inequality is gradually equalised by collisions of electrons, which is equivalent to the diffusion of the quicker-moving electrons amongst the slower-moving ones. Hence facility of electronic displacements implies good conductivity for heat.

12. Conduction of electricity is effected by the movements of the free electrons under electromotive force during their free period. This unidirectional drift of electrons is superimposed on the irregular natural motion of the electrons.

13. A current of electricity is measured by the number of electrons per unit volume multiplied by the static charge of each and by the mean unidirectional velocity or by Nev. The electronic charge is 3×10^{-10} of an electrostatic unit or 10^{-20} of an electromagnetic unit.

14. If, then, we create by E.M.F. an electronic drift, the increase in electronic kinetic energy or in sensible heat must be proportional to the square of the current, and this is Joule's law. Joule's law affords proof, therefore, that the sensible heat is due to electronic *vis viva.*

15. The mean free path of a free electron is, in most metals, about $\frac{1}{200}$ of 1μ or $\frac{1}{200000}$ of 1 mm. In bismuth it is about one hundred times greater. The mean free path of a gas molecule at 760 mm. is about $\frac{1}{10}$ of 1μ or $\frac{1}{10000}$ of 1 mm.

16. Rise of temperature, by accelerating electron velocity, shortens the time of free path, and therefore decreases the time during which electron drift or current can take place. Hence it increases resistance, which is measured by the ratio of E.M.F. to current.

17. Good conductors of electricity are therefore good conductors of heat, because in both there is either large free path or small mean velocity along that path. In both cases the large mean free path or small mean electronic velocity implies facility for electronic drift or opportunity for equalisation of kinetic energy, which implies good conductivity for heat and for electricity.

18. Moreover, it can be shown that the ratio of conductivity for heat to conductivity for electricity increases with and as the absolute temperature. At low temperatures the electric conductivity becomes very large. The calculated ratio for copper and many other metals agrees with experiment.

19. An electron radiates only when it is being accelerated or retarded. Hence at each collision it radiates, and rise of temperature, by increasing electronic velocity and number of collisions, increases radiation. Boltzmann and Larmor have both deduced theoretically Stefan's law. Also Jeans has derived Wien's and Stefan's laws from the electronic hypothesis.

20. We can also show by elementary reasoning that the theory of electric conduction which assumes the existence of free electrons in the metal with a certain short interval of time between the collisions of electrons and atoms tends to Ohm's law—viz., that the current is independent of the electromotive force at a given temperature. Hence the hypothesis generally is supported by the facts of Nature, and may be employed to visualise the processes and assist in forming clear conceptions of what takes place.

For fuller information on these important points of theory the reader may be referred to the following works:—

"The Electron Theory," by E. E. Fournier d'Albe.

"A Treatise on Electrical Theory," by G. W. de Tunzelmann.

"The Theory of Electrons," by H. A. Lorentz, where the reader capable of following mathematical discussions will find the most authoritative exposition of the applications of the electron theory to the laws of electric conduction and radiation.

THE STEEL INDUSTRY IN ITALY.

The steel industry of Italy of late years has developed considerably, having been previously so unimportant that nearly the whole of the iron ore from Elba, on which the industry is more or less dependent, was exported to the United Kingdom. The most important steel works of the country are now those at Terni, of the Siderurgica at Savona, the Alti Forni at Piombino on the mainland, opposite the island of Elba, and the Ilva Company's works at Naples. The Terni, the oldest of these, with a capital of about £725,000, owes its inception to the late Signor Brin, Minister of Marine, under whose auspices, with the aid of large advances of capital from Government, it arose in 1884. The object in view, which has been successfully attained, was to render Italy independent of foreign

countries for its armour-plating and other naval requirements. The Siderurgica, with a capital of about £1,280,000 between shares and debentures, was formed in 1900. Its operations are chiefly limited to the conversion of pig iron into steel, and to working the metal thus obtained into rails, etc. The pig iron is derived nearly all from the United Kingdom, Germany, and Spain, and the coal from the first two. The works of the Elba Company are situated at Portoferrajo, the chief town of the island, which possesses an excellent natural harbour. They comprise three blast furnaces, two Bessemer converters, and coke ovens. Both ingots and pig metal are shipped off, chiefly to Savona, where finished steel products or castings are manufactured therefrom.

Though ostensibly separate and distinct undertakings, the Terni, Savona, Elba, and Ilva companies, with a collective capital between shares and debentures (at their full value) of £4,560,000, are linked together, and constitute a sort of merger or steel trust. The works at Savona, Portoferrajo and Naples, although so far apart, are under the personal direction of one and the same managing director, Signor Cesare Fera. The Elba mines are thus called upon to supply yearly about 600,000 tons of ore, undoubtedly a formidable output for mines which are reputed to contain only nine or ten million tons of ore. Their exhaustion would thus seemingly be a question of another fifteen years' working, but it is stated that fresh deposits have recently been discovered in the island which will extend the life of the mines, in addition to some in Sardinia.

THE GUANO-PALM INDUSTRY IN HONDURAS.

It is the custom in Honduras, when clearing land for cultivation, to burn all growths, except marketable timber, and as guano-palm was considered valueless large quantities were destroyed. Notwithstanding this the supply is abundant. Prior to 1908 the value of this timber was practically unknown. On one of his periodical trips to Honduras for cargoes of dye and hard woods, the captain of a schooner was handed a piece of this wood for examination. Realising the possibilities for the development of an industry, he carried a larger sample to his principals in New York. On each successive voyage thereafter his cargoes have included large quantities of guano-palm logs. The tree requires a damp marshy soil for its best development, and frequently attains a diameter of more than 2 ft. It is not marketable above that size, however, while the minimum is 8 and 10 inches. It flourishes and is abundant along the lowlands of the coast. The wood in its natural state is exceedingly porous and light, but damp and soggy. To prepare it for commercial use it is put through an evaporating process to extract the moisture, thereby greatly reducing the weight, so that it is not only lighter than ordinary cork, but a given weight is capable of being compressed into much smaller bulk. It is used pulverised and in slabs. Lately the commercial possibilities of the wood have become known, as indicated by advertisements in trade journals offering for sale life-preserving equipments made from guano-palm. Planters in Honduras are awakening to the possibilities of the tree, and one banana grower, who annually clears a large acreage for banana cultivation, is about to send a representative to close a contract with New York importers for a cargo of 150,000 ft. of guano-palm. A recent enquiry from the same market calls for 1,000,000 ft. The greatest drawback to the rapid execution of orders is the difficulty of transportation.

THE ECONOMIC CONDITION OF JAPANESE SAGHALIEN.

The Island of Saghalien was occupied by the Japanese forces in 1905, and their possession of the island south of the fiftieth parallel was confirmed by the treaty of peace with Russia in October of the same year. Of the industries of the island, the one that has from old times been the most developed and important is fishery. The development of the herring fishery has of late been especially marked, and is now at the head of the industry, and next to it comes the trout and salmon fishery. With respect to the catch of these fish, the special right of laying nets, that is, the seine fishery right, is granted within definite limits of the sea, while for other fish it has been decided to allow fishery in common. Cod fishing is carried on to a considerable extent, and this is followed by crab fishing. The latter has developed remarkably, and the crabs caught are all tinned and chiefly exported to America. About 10,000 cases (four dozen in a case) of tinned crab were produced in 1909. To prevent the diminution of important fish, such as herring, trout, and salmon, the number of fishing grounds off the island is restricted to three hundred and forty-two. An experimental fish farm has been established on the western coast, where investigations and researches of various kinds are being carried on. Upon the cession of the island to Japan, general investigation was made respecting its agricultural capacity, with the result that it was ascertained that there were many tracts suitable for cultivation and pasturage, and that both soil and climate are favourable. Accordingly, since 1906, agricultural settlers have been quartered in suitable localities, and domestic animals and various seeds have been provided for them. At present, according to a Japanese report, the chief products of the island are wheat, barley, oats, rye, pease, potatoes, hay, and vegetables. According to the investigation of the mining products of the island made since 1905, the principal product of the island is coal, next to which are alluvial gold and iron pyrites. Coal is especially abundant, and is of good quality. There are three important coalfields in the island, namely, the

northern, the middle, and the southern coalfields, besides many others of less importance. The greatest of them is the middle coalfield, which extends from the River Pusutaki, a tributary of the Susuya, to the River Tomarioro, the length being sixty miles, and the width varying between one and three miles. The northern coalfield lies along the eastern side of the mountain range of Karafuto, extending from near the mouth of the River Poronai to the Russian boundary. The southern coalfield is situated in the central portion of the Notoro peninsula. Alluvial gold abounds in the beds of the rivers which come down from the Taraika, Susuya, and Shiretoko mountain ranges. Iron pyrites are found in large quantities in the Notoro peninsula. In 1907 oil was discovered in the neighbourhood of Tokombo and Arakoi on the western coast. The forests are virgin, and of an extent unequalled in other parts of the Japanese Empire.

THE WOOD-ALCOHOL INDUSTRY IN GERMANY.

The wood-alcohol industry in Germany made slow progress until 1880, when the law providing for the denaturation of alcohol was passed, but about the same time the importation of wood alcohol and pyrolignite of lime from the United States began, and a number of the wood distilling firms merely bought up these imported raw products and manufactured them into acetic acid, methyl alcohol, and denatured wood alcohol. The largest concerns, however, soon established their own distilling plants in the thickly-wooded surrounding countries of Galicia, Hungary, and Russia, and imported their raw products to their refining plants in Germany. Exact figures of the production of wood alcohol and pyrolignite of lime are not published, but according to a reliable estimate there were produced in a recent year, in Austria, Hungary, and Germany, about 6,500 metric tons of the former and 27,000 to 28,000 metric tons of the latter. The industry has also suffered somewhat of late years on account of the competition with the great volume of denatured potato and grain alcohol produced in Germany. The fact that deciduous varieties of wood are comparatively scarce in Germany is another reason why the wood-alcohol industry is not so far advanced. Chemists and distillers state that wood from coniferous trees produces only about one-half the wood alcohol and pyroligneous acid produced by wood from deciduous varieties, and that the profitable distillation in the former case depends upon the quality and quantity of the pine oil and tar obtained. On account of the costliness and general application of these woods the stumps of coniferous trees are practically all that are distilled. The distillation of sawdust and wood refuse has not proved profitable, because practically all these products in Germany come from coniferous woods, which not only produce little alcohol and pyroligneous acid, but very little tar and pine oil. The charcoal obtained in the distillation of sawdust, which is the only other product of possible commercial worth, is comparatively valueless, because it is in powder form, and efforts to obtain it in briquette form have as yet proved unsuccessful.

ARTS AND CRAFTS.

The Exhibition at the Design Club.—The Design Club, which has recently moved into new and more picturesque quarters at 106, Great Russell Street, held an exhibition of members' work early in June. As the greater number of the artists belonging to the club are designers for various kinds of manufacture, it is not often that there is a chance of seeing their work with any very certain knowledge of who is really responsible for it. The little show at the club-rooms, however, afforded an opportunity both of seeing what certain men are doing, and of realising the lines along which some of the best trade designers are moving. Amongst the repeating patterns shown at Great Russell Street may be mentioned some interesting wallpaper and cretonne designs by Mr. Lindsay P. Butterfield, more closely allied to "the styles" than a good deal of his work; a little group of patterns by Mr. Sidney Hayward, one or two of which were more restrained and less naturalistic than the work one habitually connects with his name; some good carpet designs and sketches by Mr. Alfred Carpenter; some rather effective velveteens by Mr. Napper; a few clever, if not very tasteful, patterns by Mr. Wilcox; and a couple of very dainty and workmanlike little sketch designs for tablecloths, destined for round and oval tables, by Mr. Gordon Hunton.

Amongst the designs for stained glass were two or three figure panels by Mr. T. Erat Harrison, and some very decorative and convincing ships by Mr. E. Ingram Taylor. Mr. Amor Fenn's episcopal cross and his design for ironwork at the Wesleyan Church House were both distinctive and workmanlike, and Mr. Alfred de Sauty's bookbindings, without shouting in any way, compelled attention by their individuality, their freshness, and the unusual appreciation of balance and proportion displayed in them. The original of the Garden City poster by Mr. Tom Taylor proved how much better a good original is than even the most successful reproduction can hope to be, and Mr. C. F. A. Voysey's rug design was a very clever and amusing bit of artistic playwork. The names of one or two of the members of the Design Club are familiar to most educated people with any pretensions to artistic culture; those of the majority are known only to the few immediately interested in applied design. The exhibition, when one considered it in that connection, gave one rather a feeling of depression. Here is accomplished and often really artistic work done by men of whom the general public have never heard, while the

names of half a score of workers in the artistic crafts, far less accomplished and no better artists, are quite well known.

Textiles and the Coronation.—The Coronation has, of course, been a good opportunity for seeing what the British textile manufacturers are doing. Their forces were called into action not only for the decoration of Westminster Abbey, but also for the clothing of those who took prominent part in the ceremony, and there seems to have been a very strong desire on the part of those concerned that, at any rate on an occasion so bound up with the nation's life as the crowning of its King, an opportunity should be given for British workers to show what they could turn out. The patterned carpet in two shades of blue laid in the centre aisle of the nave was made by Messrs. Templeton, and is certainly a fine bit of weaving, whilst the colour and texture of the plain carpet by the same firm which covered the floor of "the theatre" left nothing to be desired. Messrs. Lister's velvet (deep blue on a buffish ground shot with silver), which covered all the galleries of the Abbey, and formed the main part of the decorations, was a good copy of a worthy Italian model, and did not clash with or unduly pronounce itself against the surrounding stonework. The fine tissue hangings on either side of the altar, whose many colours blended into a most harmonious whole, reminiscent of the damask background to some primitive Italian picture, were woven by Messrs. Warner & Sons, while the very happy rendering of the seventeenth-century Genoa velvet on the chair at Knole, which covered the recognition chairs, was by the same manufacturers. The effect of the deep green (almost black) and buffish velvet on the pinkish red ground is fine in itself, and is wonderfully helped by the skilful employment of the "Terry" outline. The design of the damask for the thrones of the King and Queen is a very good example of William Morris's work, and its colour, which looks a trifle dingy in the subdued light of the Abbey, is quite beautiful when seen in the bright sunlight. The large and dignified woven patterns of the copes of the Archbishop of Canterbury and the Bishop of Peterborough were taken by Messrs. Warner from old Italian designs, but the patterns are thoroughly good, and the effectiveness of the open ogee pattern worn by the Bishop of Peterborough owes a great deal to the skill with which it has been treated. It cannot, perhaps, be said that the Coronation has done much to stimulate original design in textile fabrics. A good many of the more serious and dignified patterns are certainly founded on old models, but the greater number of the sprig designs and other light decoration used for ladies' dresses are new, and these have afforded an oppportunity, which Messrs. Warner, and probably other firms, have not been slow to take, of showing what beautiful work can be done in England in the way of brocading on a damask ground in coloured silks and gold and silver thread by means of an extra shuttle. When effects like this can be got in the loom, a certain kind of embroidery ceases to be worth while.

Embroidery for the Coronation.—In one way and another the Coronation has been responsible for a good deal of embroidery, good, bad, and indifferent. The most monumental pieces of needlework are, of course, the frontal and dossal presented to the Abbey by the King and Queen, and carried out by Messrs. Morris & Co. from designs by Professor Lethaby and students of the Royal College of Art. The time allowed for the working of these important pieces of embroidery has necessarily been short, and when one remembers that so late as the beginning of the year it was commonly said by those who might be supposed to know that the work had been entrusted to quite different hands, it is surprising that it has been carried out so satisfactorily. On the other hand, it is rather to be regretted that in the twentieth century our ideas of fitting altar hangings for the great Abbey Church of Westminster cannot soar beyond the reproduction of the setting out of a late fifteenth-century frontal, which, though good in its way, is not remarkable for any particular beauty of design, and the introduction into these surroundings of archaic figures suggesting, alike by their drawing and their workmanship, a considerably earlier date. Of course, a conspicuously up-to-date design would have looked singularly out of place in the Abbey, but it would surely have been more fitting if the gift which will go down to posterity as commemorating the crowning of a twentieth-century king had borne some more characteristic marks of its own period. The embroidered arms in the thrones of the King and Queen and the chairs of the Duke of Connaught and Prince Arthur of Connaught have been executed by Messrs. Morris from designs by the Rev. E. E. Dorling, and they are good examples of heraldic treatment, free from the heavy padding and various other vulgarities which so often mar work of this kind. The great part of the design has in each case been carried out in stitchery, but the garters, the mounds, and the ermine are in appliqué.

The Prince of Wales's chair, for which Messrs. White, Allom are responsible, deserves separate mention. The problem before Messrs. Morris was how to get a large quantity of embroidery carried out at short notice in a creditable manner, and they have solved it satisfactorily enough. What Messrs. White, Allom have set themselves to do has been to see how perfectly the design on one chair could be executed, and their success has been complete. The Prince of Wales's arms, worked for them, from the design of Mr. Dorling, in the embroidery room of the Community of S. Mary the Virgin at Wantage, is a wonderful bit of workmanship. The drawing throughout is well preserved. The heraldic beasts are full of vigour and go, and the unicorn, executed in silver thread couched with a variety of tints, is as full of colour as is the pearly silver lining of a delicate shell. The texture of the ermine, too, is cleverly and not too

naturalistically rendered in stitchery. In short, the whole thing is a good example of the very best type of heraldic work.

Students' Carving.—The armoire presented to the King and Queen by the students and teachers of the School of Art Wood-carving, was on view at 39, Thurloe Place for a few days before it went to Buckingham Palace. It was designed by Mr. Grimwood, the chief instructor, and though more or less in the style of François I. work, it bears traces of its modern origin. The cabinet was planned so as to give a number of students in different stages of progress an opportunity of showing what they could do; and some of the mouldings and other simpler parts were executed by students almost at the beginning of their careers, whilst the linenfold side panels and the Royal Arms of the central door gave ample scope to more advanced workers. The carving, which was the work of *bonâ fide* students, gave a very good proof of the thoroughly practical teaching provided by the school.

EMPIRE NOTES.

Imperial Unity.—Among the many recent contributions to the discussion of the subject of Imperial unity, one of the most important is that supplied by the publication of Mr. Richard Jebb's new book on "The Imperial Conference," in which he gives a carefully-compiled history of the proceedings of the five conferences, commencing in 1887, tracing their development as a constitutional institution. He has also dealt with some of the events in the intervals between the meetings, in order to present a complete and comprehensive view of the difficulties which have to be met if the movement is to be the success we all desire. There is no question that the holding of these conferences has done much to promote union between the various parts of the Empire, but a great deal more will have to be done before the Empire attains that organic unity which is the ideal of the Imperialist. The present conference clearly shows that the Oversea Dominions will not be content with occasional pourparlers if they are to be regarded as partners in the business of Empire, who must bear their fair proportion of its burdens. As a step towards the solution of the problems which surround the question of Imperial unity and how it may be best effected, the study of Mr. Jebb's work is necessary, and its issue therefore timely. The same may be said, though the theme is essentially different, of Mr. Charles Bright's book on "Imperial Telegraphic Communication," as upon the facilities of telegraphic communication throughout the Empire much depends for the creation of that spirit of union which must be based upon mutual understanding, which can only be brought about by close and constant intercourse.

An Australian Solar Observatory.—Reference has been made in these columns, on more than one occasion, to the necessity of establishing a solar observatory in Australia, so as to complete the round-the-world chain of observatories, in order that the sun may be watched throughout the whole of the twenty-four hours. A definite forward movement has now been taken to this end by an appeal which has been issued by the British Empire League for funds for the purpose of helping to establish the Australian observatory. It is hoped that the appeal will be successful, and that the balance required, £6,000, will speedily be raised. Such an observatory, it is stated, would ensure that the four great centres of solar work—the British, American, Indian and Australian—would be conducted by English-speaking peoples. In this connection it is interesting to note that the Canadian Government are arranging to establish an observatory in the Cariboo district of British Columbia, which is to be equipped as thoroughly as that of Toronto, so that it may be of service to the new university at Vancouver.

A Co-operative Scheme for Alberta.—Mr. J. L. Stephens, a United States capitalist, has organised a Co-operative Farming Company for Alberta, which, in some of its features, is similar to a scheme of federative farming reported in the columns of a London journal recently. Under Mr. Stephens's scheme, although there is but one farm, there may be many proprietors. These may be composed of the employees themselves, who will be paid for their work according to its value, and who will also be able to draw their share of dividends for the money they may have invested in the undertaking. The farm will be under the care of an expert scientific farmer, who will be expected to give instruction to those who may enter into the service of the company as employees, and yet at the same time be themselves part-owners of the estate. In this way a man who has had no previous experience on the land may acquire a knowledge of farming, and eventually be able to make a start on his own account, using the capital which he may have invested in the company for that purpose. Of course, very much will depend upon the management, but the principle of the proposal, which is an important development of the share system in vogue in various parts of the Empire, appears to be a sound one.

A Canadian School of Commerce.—In the coming autumn, a school of commerce, similar in character to the schools established in London, Birmingham, Harvard, and Chicago, will be opened at McGill University, Montreal. The object of the school is to enable young men who cannot take a full college course before entering business to supplement their school education by a two years' course of special studies. The decision to open a school of the kind was reached after experiments on a small scale, during the last few years, which revealed a demand for such teaching by school graduates.

Exploration in Western Australia.—Mr. C. P. Conigrave, F.R.G.S., who was formerly Assistant

Curator of the Perth Museum, is now leading an exploring party in the north-west of Western Australia. He reports that in his trip across the Ord River, through the pine forests near the South Australian border, he has found the fauna and flora to be prolific, but he regrets to note the great destruction, in the Wyndham district, of the white egret, for the sake of its plumage, and suggests that steps should be taken to put a stop to it. Mr. Conigrave's party is following up the work done, a few years ago, by Mr. F. S. Brockman and others, but he proposes to explore a part of the country into which no white man has yet entered—a country well watered and fertile, which, in years to come, will prove to be one of the richest districts of Western Australia.

Shipbuilding in Victoria.—Melbourne is evidently determined not to allow her great competitor, Sydney, to dominate the shipbuilding enterprise of Australia. It is proposed, therefore, that a start be made at Williamstown with the establishment of shipbuilding yards, and official inquiries are to be instituted with the object of discovering the best means of improving and developing the outer ports of Victoria. The Premier, the Hon. J. Murray, who is at present in London, says, "We must have our own properly-equipped shipbuilding facilities, in order that we may be able to compete with any of the other States in this direction, and to deal not only with our own mercantile marine, but with any other large shipbuilding projects which may be afloat."

Emigration.—The standing committee appointed by last year's conference on emigration, the holding of which was first suggested at a meeting of the Colonial section of this Society, has issued a report, which has been submitted to the Imperial Conference. In it they recommend that full consideration should be given to the problem of emigration within the Empire, and that, should the Imperial Conference be unable, as the case has proved, to attend to the subject in detail, a subsidiary conference should be formed for the purpose. They further suggest that an official committee be appointed representing the various emigration societies of the United Kingdom, the chairman of which, and representatives of the chief departments concerned, should be nominated by the Government. The Dominions Governments might also nominate representatives. The functions of the proposed committee would be, among other things, to co-ordinate the emigration societies of the United Kingdom—a very desirable undertaking—and to deal with the labour exchanges, distress committees, and other bodies, on all matters connected with emigration. In an appendix the report treats of the emigration of single men and families, of women and of children, and emphasises the special importance of redressing the anomalies of female population in the Mother Country and the oversea States, and of encouraging the emigration, under properly constituted authority, of workhouse and orphan children. In view of the immediate need of Australia, New Zealand, and Canada for people, and of the prevalent unemployment and distress in the homeland, which is persistent if in degree variable, the suggestions of the standing committee are worthy of the careful consideration of the home and colonial authorities, and of all who are interested in the maintenance and defence of the Empire.

Tin in Rhodesia.—A discovery of tin in Rhodesia, near Salisbury, is reported. The ore has been located over an area of twenty square miles, and is said to give results up to 5 per cent. of metallic tin. The value of the find is stated to be confirmed by engineers and tin experts. If the operations for proving the ore, which are now in progress, turn out successful, the discovery should be of great value to Rhodesia and to South Africa.

NOTES ON BOOKS.

Manual of Library Bookbinding. By H. T. Coutts and G. A. Stephen. London: Libraco, Ltd. 7*s.* 6*d.* net.

Though many books have been written on bookbinding, they all, or nearly all, deal with that more distinguished section of the craft which devotes itself to the encasing of books in leather, and the decoration of the encasement. And yet, for every single volume that is carefully and honourably clothed in the more ancient manner, there must be thousands which are rapidly sewn and squeezed and packed into their shells of card and calico, to be hurried out into the world for a fleeting and transitory life. Despite the difference in intention and result, the new process is no less skilful than the old, but the skill has passed from the workman to the designer of the machinery. In this, as in all modern industrial processes, the workman has become an operative. He does not execute any work at all. He "operates" or "minds" a machine which does a part of the work. The finished article is the result of the efforts of a number of machines, and the better the machine the less the intelligence required to "mind" or look after it. The manufacture of a modern book, like the making of a modern bale of calico, requires the service of a number of machines of the highest ingenuity. The nature of these machines, the manner of their employment, and the results of their labours form the subject of the volume under review. It gives a very full and clear account of the various methods by which a book is turned out and of the materials employed. It provides much useful information and many practical hints for the benefit of librarians and others who have to employ binders; and, on the whole, it may be recommended as a very complete and serviceable treatise on a subject of interest and importance.

SILK: ITS PRODUCTION AND MANUFACTURE. By Luther Hooper. London: Sir Isaac Pitman & Sons, Ltd. 1s. 6d. net.

This volume forms the eighth of the series known as "Pitman's Common Commodities of Commerce," an excellent set of little handbooks which have already dealt with coffee, tea, cotton, sugar, oil, rubber, and iron and steel. Mr. Hooper, who is well known as a writer and lecturer on the subject of weaving, gives a very concise and interesting account of silk. Starting literally *ab ovo*, he describes the various species of silk-worm, their anatomy, and the manner in which they are cultivated; this is followed by chapters on the history of silk and sericulture, reeling from the cocoons, silk throwing and winding, dyeing, varieties of the silk thread, ancient silk weaving, the webs of China, satin damask weaving, and so on until the last chapter, which treats of modern silk weaving. The book is written in a very simple style, which, with the illustrations, renders it easily intelligible, even to those with no technical knowledge of the subject.

GENERAL NOTES.

INTERNATIONAL CONGRESS FOR SANITARY DWELLINGS, DRESDEN.—The Third International Congress for Sanitary Dwellings will be held at Dresden from October 2nd to 7th, 1911. The congress is divided into nine sections as follows:—

Group A: General.—Section I. Town-planning (building, forms of country settlement, garden cities, width of streets, height of building). Section II. Construction of buildings (planning, distribution of space, building material, foundations, basement, kitchens, lavatories, floors and ceilings, staircases, lifts and roofs). Section III. Internal arrangements (lighting, heating, ventilation, furnishing). Section IV. Sanitation (cleaning, removal of refuse, disinfection).

Group B: Dwelling Houses.—Section V. Dwelling houses in towns. Section VI. Dwelling-houses in the country.

Group C: Special Kinds of Dwellings.—Section VII. School buildings, boarding-schools, prisons, hotels, lodging-houses, hospitals, convalescent homes, baths, churches, theatres, and other public buildings. Section VIII. Workrooms and workshops, means of communication and transit (railways, tramways, ships, vehicles, etc.).

Group D.—Section IX. Legislation, executive, statistics, etc.

INTERNATIONAL SOCIETY FOR THE PROMOTION OF COMMERCIAL EDUCATION.—A meeting, organised by the International Society for the Promotion of Commercial Education, is to be held in London from July 24th to August 12th. It consists of some fifty lectures and a series of visits to places of commercial importance in and around London. The lectures are to be given each morning at the London School of Economics. They will describe the actual conditions and methods of British industry and commerce. The lecturers are leading business men and university teachers who have a practical knowledge of the subjects upon which they are lecturing. Among them are Mr. Mackinder, M.P., Mr. Lees Smith, M.P., Sir Laurence Gomme, Mr. Steele (of Parr's Bank), Mr. Birgood (of the Edinburgh Life Assurance Company), Mr. Hirst (editor of the *Economist*), Mr. Jeans (editor of the *Iron and Coal Trades Review*), Mr. Dunstan (of Wye Agricultural College), Mr. Ben Morgan (Trade Commissioner to Australia), Mr. Chiappini (Trades Commissioner to South Africa), and other well-known men. In the afternoons the students will visit docks, warehouses, factories, etc., and a whole day excursion to Birmingham will be made. The meeting is under the patronage of the London Chamber of Commerce, the London County Council, the University of London, the Royal Society of Arts, and other societies. A strong executive committee are arranging the details of the meeting; they expect to have at least 150 students. The fee for the course of lectures is £3. The committee would be glad to know of factories, warehouses, and other places of commercial interest in London which may be visited by the students. All who are interested in the meeting are invited to write to the Organising Secretary, Mr. E. Cleveland-Stevens, at the London School of Economics, Clare-market, W.C.

THE RUSSIAN SALT INDUSTRY.—The production of salt is classed among Russia's principal industries, and it may be said to be centred in the Odessa district, two-thirds of the total output being produced there. It is the production of salt in that district which has made it possible almost to exclude the foreign article from Russian possessions on the Baltic, and which will probably exclude it from the White Sea as well. The beginning was made last year to export from Eupatoria its best salt, which had been kept for several years in open stocks, to the Far East, there to be used in curing salmon and cod, to supersede Japanese salt. In Russia's easternmost possessions, on the Vilui River, an affluent of the Lena, there are wonderful masses of the purest rock table-salt overhanging the river to a height of 150 feet or more, but the means of transport are not likely soon to attain that development which will permit this salt to be shipped to the Pacific coast. The little increase in the output of table-salt in Russia is explained by the comparatively small requirements in the country for the production of soda and kindred industries. There are three ways in which salt is produced in Russia, viz., raking out the salt crystals which fall to the bottoms of the numerous salt lakes during dry seasons, rock-salt mining, and the evaporation of the brine obtained from deep wells. The total amount of salt produced in Russia in 1909 was 2,489,000 tons.

Journal of the Royal Society of Arts.

No. 3,060. VOL. LIX.

FRIDAY, JULY 14, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

CHAIRMANSHIP OF COUNCIL.

On Monday, the 10th inst., at their first meeting, the Council elected LORD SANDERSON, G.C.B., Chairman for the ensuing year.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

THE APPLICATIONS OF ELECTRIC HEATING.

By Professor J. A. FLEMING, M.A., D.Sc., F.R.S., M.Inst.E.E.,

Pender Professor of Electrical Engineering in the University of London.

Lecture II.—Delivered March 13th, 1911.

THE APPLIANCES AND PROCESSES OF ELECTRIC HEATING.

The simplest method of heating a substance electrically is to pass an electric current through it. If the body has sufficient but not too much conductivity, it will be heated, and if we can prevent this heat from being removed we can raise the temperature to any degree. This method is called *resistance heating*. If the substance under treatment is not a conductor, it can be heated by passing the current through another resistance in contiguity to it. This resistance must be refractory and non-oxidisable at high temperatures. Very few materials possess all the qualities necessary for such a heating resistance. Platinum is almost the only pure metal which has them all.

Certain baser metals, such as iron, nickel or alloys, can be used up to temperatures not much above red heat, but are slowly acted upon by the atmosphere. An alloy called nichrome—a nickel chromium steel—is, however, extensively used as a heating resistance, and seems to endure heating to a red heat for a considerable time without destructive oxidation. A material called silundum has also come into use lately as a resistance material. It is prepared in an electric furnace. Carbon rods are packed in a crucible with a material which is principally silicon carbide (carborundum) and boron carbide, and when heated to 1,600° C. or 2,000° C. these carbides volatilise and impregnate the carbon. This converts it superficially into a material which does not oxidise at a red heat. The resistivity of silundum is approximately three times that of carbon. When prepared the carbon rods, now called silundum, are fixed in a metal frame, and can be heated without injury to a bright, red heat.

Granulated graphitic carbon, mixed with carborundum and certain silicates, is also used as a resistance material, and is known under the name *kryptol*.

Except in those cases in which the material to be acted upon itself forms the conductor, we may say that the above short list comprises almost all the materials suitable for forming the resistance in which the heat is generated by the passage through it of a current. The current may be created in this conductor either by the direct application to it of an external electromotive force, or it may be induced in it by the action of an alternating current in a neighbouring circuit. This last method is called *induced heating*. The direct and inductive methods can be combined together. The second method, although first in point of priority for producing heat electrically, is by means of an electric arc.

We may expose a substance to the direct radiation from a powerful electric arc or arcs, and in that way raise it to a high temperature, provided it is a black body or good absorber. On the other hand, we may form the arc against the substance to be heated by making it one of the electrodes of the arc, and, lastly, we may combine together the resistance-heating and arc-heating by making the substance to be

heated one of the electrodes, forming the arc against it, and then bringing the other electrode into contact with the substance to be heated.

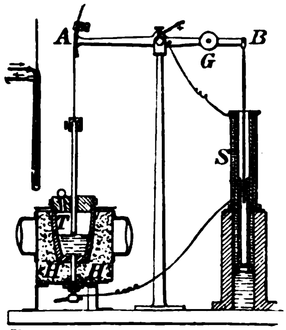

FIG. 21.—SIEMENS' EARLY ELECTRIC ARC FURNACE FOR STEEL MELTING.

As this was one of the earliest methods in point of time, we shall begin by considering this electric *arc heating* in its various forms.

Sir W. Siemens, in 1879, was the first to construct an electric arc smelting furnace, and apply it in metallurgy. Through the bottom of a crucible of fireclay or plumbago he passed a hard carbon and connected it to the positive pole of a direct current dynamo (see Fig. 21). The crucible was filled with fragments of iron or steel. The negative pole was a water-cooled iron or copper rod, which could be raised or lowered through a hole in the crucible cover. On making contact an electric arc was formed, which soon melted the metal. Using a current of 36 amperes, Sir W. Siemens found he could melt 22 lbs. of steel in an hour, and his estimate of the cost was that with a steam-driven dynamo 1 lb. of coal burnt in the furnace of the boiler would melt 1 lb. of steel in the crucible. This proved that in economy of working the electric furnace could compete with the regenerative gas furnace. Although this encouraging result was arrived at in 1879, it was not until the production of large electric currents had become an every-day matter that attention again became directed to the advantages of the electric furnace. Nearly twenty years later, in 1898, the subject was again taken up by Major Ernest Stassano, an Italian Artillery officer, who has devoted much time during the last twelve or fifteen years to perfecting a form of arc furnace for steel-making. In its most recent form it consists of a drum-shaped iron vessel, lined with refractory brick, and closed by a dome-shaped roof (see Fig. 22). Two or three carbon electrodes are inserted through the sides, these meeting in the middle, and being moved in or out by means of hydraulic cylinders. Between these carbons a single or three-phase arc is formed. The metal to be melted is placed in the hearth below the arcs, and the whole furnace is supported in an inclined position and rotated so as to mix the contents when fluid.

In the Stassano furnace the heating is produced by radiant heat from the arcs, so that the metal itself is not contaminated by touching the incandescent electrodes. As on this occasion we are concerned with the methods of heating rather than the results, we shall defer until the next lecture any discussion of the economical aspects of this furnace when used for steel manufacture. The next type of arc furnace is that developed by M. Paul Héroult, who in 1879 directed his thoughts to this matter. Héroult was previously well known as the inventor of a process of making aluminium, to which we shall refer later; and he then turned his attention to the production of special alloys of iron with other metals, called ferro-alloys, by means of the electric furnace.

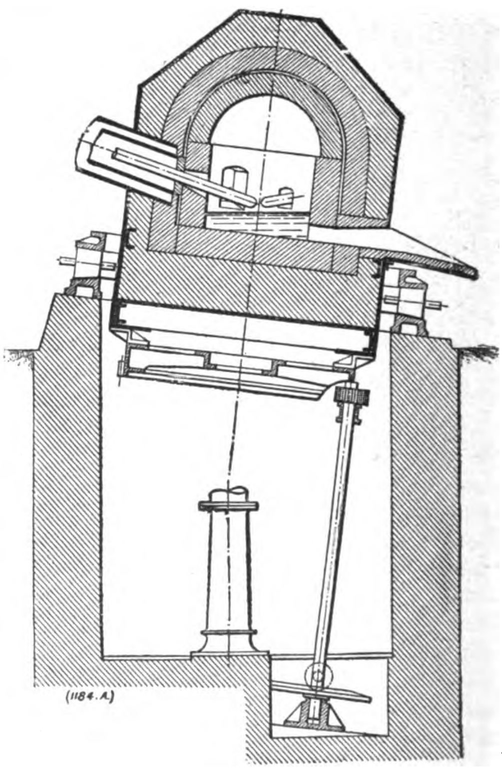

FIG. 22.—STASSANO ELECTRIC ARC FURNACE FOR STEEL MANUFACTURE.

Héroult has designed two distinct forms of electric furnace—one a form of electric blast furnace for the production of pig-iron from ore,

and the other a tilting crucible furnace for steel manufacture.

The latter consists of a sort of iron vessel, well lined with refractory bricks, made of magnesite or dolomite. The furnace is mounted on trunnions, by means of which it can be tilted, and the contents emptied over a spout. There is also an inlet for an air blast. Over the furnace, and attached to it, there is an insulated support for carrying two massive carbon electrodes, which project through holes in the lid of the furnace and can be raised or lowered at pleasure by gearing driven by electric or hydraulic power. One of these electrodes is the positive and the other the negative carbon (see Fig. 23).

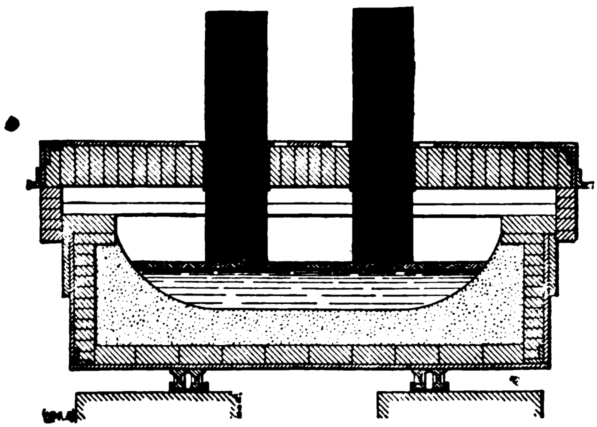

Fig. 23.—Héroult Electric Arc Furnace.

The furnace is worked in the following manner. A charge of steel scrap pig-iron, iron ore and lime is thrown into the furnace and the heavy graphite electrodes are brought down to touch it. When the current is turned on the charge is heated by resistance heating, and if the carbons are then raised two electric arcs are formed against it, which speedily melt the metal. The temperature is under control by adjusting the lengths of these arcs, and an air blast can be applied if required at the same time to oxidise the impurities.

Objections have been raised to this type of furnace that the cost of renewals of the roof lining is considerable, owing to the intense and destructive heat to which it is exposed. Also that, owing to the use of double (positive and negative) carbons there is risk of short circuits across the roof, inside or outside. These objections, however, have not been a barrier to the extensive use of this type of furnace.

Héroult has also invented a form of electric blast furnace for the production of pig-iron from ore. The furnace contains three carbon electrodes, by means of which current is passed through the coke charge near the mouth, maintains this at a red heat, and by means of the third electrode current is passed up the charge through the melted metal on the hearth to the upper layers.

Under certain conditions as to cheapness of electric power and nature of ores, such an electric-blast furnace can be worked commercially for the production of pig-iron from hæmatite coke and limestone, as in the ordinary blast furnace.

The French firm of Keller, Leleux & Cie have for many years carried on the business of producing calcium carbide, ferrosilicon and other ferro-alloys by means of electric furnaces, and they have developed a type of electric arc furnace for the reduction of iron ores. In its latest form this consists of a pair of cylindrical furnaces of iron, lined with refractory bricks, connected together by a tubular hearth at the bottom

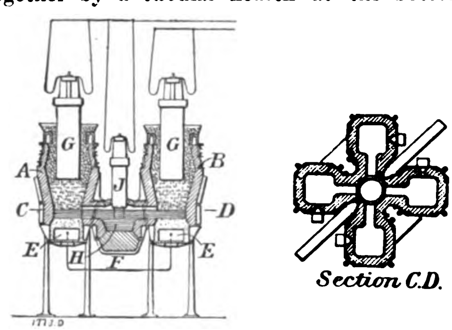

Fig. 24.—Keller Electric Furnace for Reduction of Iron Ores.

(see Fig. 24). In each of these cylinders is placed a large graphite electrode, G, and a

third, J, can, if desired, be inserted in the run of the connecting tube. The ore, coke and limestone are fed into these furnaces, and the heat generated by passing a current through the mass. As the iron ore is reduced the metal

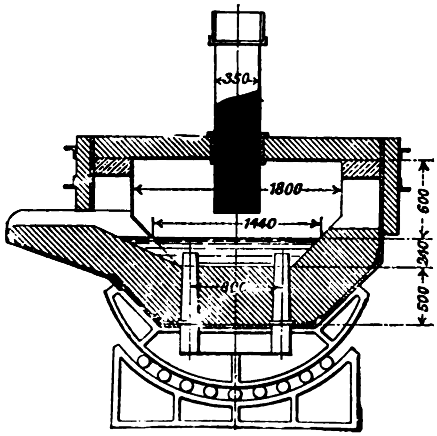

FIG. 25.—GIROD ELECTRIC ARC FURNACE.

collects in the hearth and is kept liquid by the heat generated by the current passing through it.

A steel refining furnace employed by the same firm does not differ essentially from the Héroult furnace in construction. A more recent type of arc furnace, for which greater simplicity is claimed, is that of M. Paul Girod, which is essentially a great, enlarged and commercial form of the first experimental arc furnace of Sir W. Siemens.

The hearth of this furnace consists of an oblong steel vessel with spout, lined throughout with refractory material, such as magnesite or dolomite. Through this lining pass one or more pieces of soft steel (see Fig. 25). These serve to lead the current into the molten metal lying on the hearth. These steel pieces may be made hollow, and be water-cooled. One or more carbon electrodes pass through holes in the cover or roof, but as these are of one polarity electrically, no short-circuiting can occur.

The charge can be heated by pure resistance heat by bringing down the carbon electrode to touch it, or an arc can be formed between the carbon and the charge, and either direct or alternating current can be employed. The roof or cover is lined with silica brick, the holes for the electrodes being fitted with a removable water-cooled frame. The Girod furnace can thus be either a resistance or an arc furnace, or both combined. The furnace is mounted on a semi-cylindrical base resting on steel balls in a similar concave base, so that it can easily be tilted over to pour off either the liquid slag or the metal charge itself. The ease of manipulation and of starting up, and general simplicity of construction, have given this Girod furnace a position of advantage. We shall consider more in detail in the next lecture the results of working and nature of the product.

Meanwhile, it may be said that one great advantage which these arc furnaces possess for steel refining is that they enable very hot and liquid slags to be produced. After the metal is melted and the slag collected on the surface, the carbon electrodes may be raised, so as to form the arc against the slag, and this soon renders it entirely fluid, so that it can be poured off before the charge is tilted.

On the other hand, there is always the possibility that carbon from the heated electrodes may enter the metal, and having regard to the extremely large variations in the quality of the finished steel, which are brought about by quite small changes in the percentage of carbon, it is highly desirable to have some methods of electric heating which are quite independent of electrodes, particularly as the cost of the large carbon electrodes is quite an important item in the working of the arc furnaces. This brings us to consider, then, in the next place, methods of resistance heating. These may be classified into methods of resistance heating in which the resisting circuit is the substance itself, which is being prepared, and next methods in which the resisting circuit is another material

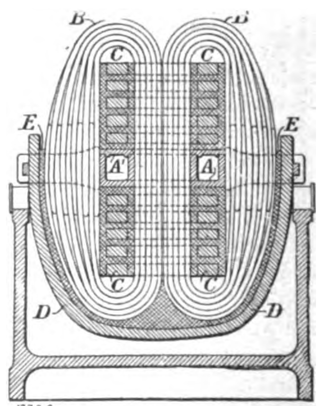

FIG. 26.—FERRANTI ORIGINAL INDUCTION FURNACE.

quite apart from the substance under preparation. Again, we may divide the methods into inductive or electrodeless heating and heating with current sent in from outside by electrodes.

The class of electric furnaces called induction

furnaces were first suggested by M. Ferranti. He proposed to construct an alternate current transformer with an iron core and primary coil traversed as usual by an alternating current (see Fig. 26). In place of the secondary coil he surrounded the iron core with an endless trough or channel, A, A, forming one complete turn of a secondary circuit. If this trough is filled with fragments of metal, and if an alternating E.M.F. is applied to the primary coil, an induced current will be created in the secondary circuit which will heat and finally melt the metal fragments forming that circuit. This current is created by the changing magnetic flux linked with the secondary circuit. Hence no electrodes are needed. The trough or channel which constitutes the secondary circuit must be made of refractory non-conducting material (see Fig. 27). Induction furnaces of this type have come into extensive use for the preparation of the higher and special grades of steel. It is not possible to secure in them such high temperatures as are producible in arc furnaces, but the temperature and operations are completely under control, and there is no possible source of contamination of the metal being melted. One of the best known of the induction furnaces is that invented in 1900 by Mr. F. A. Kjellin, a Swedish engineer. It consists of a massive rectangular iron core composed of thin plates of soft iron, insulated by non-conducting non-inflammable cement. Around this core is wound a coil of insulated wire, through which an alternating current is sent. The core is also set in a bed of refractory clay, held together by steel plates (see

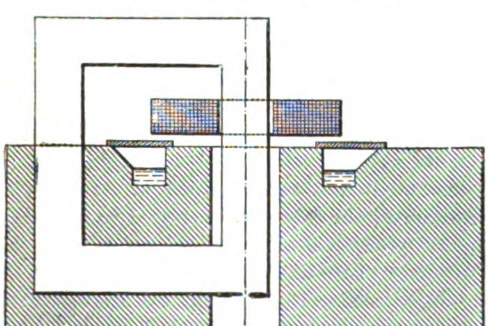

Fig. 27.—Section of an Induction Furnace, showing Annular Channel or Hearth.

Fig. 28), in which is formed a channel also embracing the core, which constitutes the secondary circuit. This channel is covered with lids of refractory material, and the whole furnace can be arranged on trunnions so as to be capable of being tilted to run off melted metal from the channel. Since such an induction furnace cannot reach the high temperature of an arc furnace, it is not adapted for working with impure material, but when charged

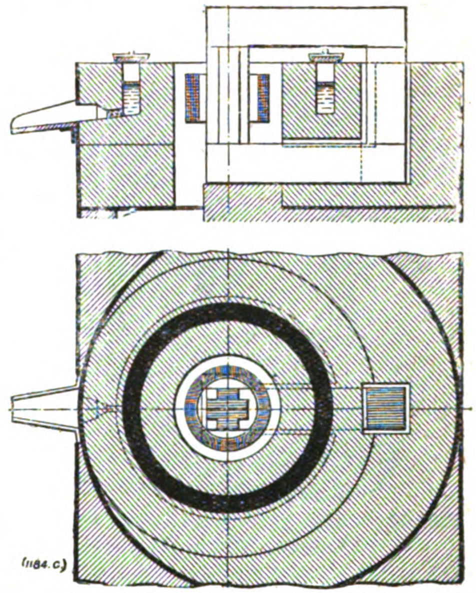

Fig. 28.—Kjellin Induction Furnace.

with a fairly high grade of steel in lumps, these can be melted and refined, freed from occluded gases, and treated with required proportions of ferro-alloys containing nickel, vanadium, chromium, tungsten, and other metals, so as to produce the special steel now so much in demand for tools and machinery of various kinds.

Another well-known induction furnace, introduced by the firm of Hermann Röchling & Co., of Germany, is the so-called Röchling-Rodenhauser furnace, in which induced heating is combined with direct-resistance heating. In the channel which forms the secondary circuit steel plates are inserted to act as electrodes, so that a current from an external source may be passed through the molten metal in addition to the current being induced in it (see Fig. 29 and Fig. 30). This external electromotive force is obtained from an incomplete metallic secondary circuit of copper which terminates in the plates of steel let in or sunk under the refractory lining of the furnace. This lining becomes conductive to a certain degree on being heated to a high temperature and so permits the current generated by the copper secondary circuit to pass through the molten metal. The effect of this is that a larger

hearth can be used, and moreover the metallic secondary circuit reduces the power factor of the furnace so that it attains a higher plant efficiency. Induction furnaces on this plan up to eight or ten tons size at one cast are at work, and are set on trunnions so as to be able to tilt off the slag or charge at pleasure. Induction furnaces have also been constructed which operate with polyphase alternating currents as well as with single phase currents.

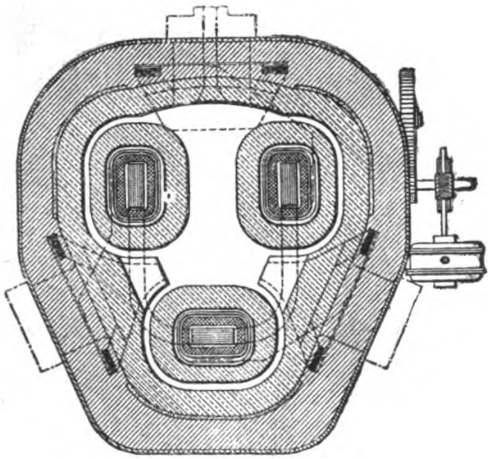

FIG. 29.—RÖCHLING-RODENHAUSER INDUCTION FURNACE. (Three phase.)

The advantages of the induction furnaces are that a high degree of purity can be obtained in the steel produced. They can be constructed up to sizes capable of making a cast of ten tons or more of metal, and owing to the action of the magnetic field in churning up the liquid metal a great uniformity in the quality of each cast can be attained. The first charge is melted by placing steel or iron rings in the channel. These are melted down and form a bath in which the rest of the materials are placed. There is a curious effect called the "Pinch effect," which sometimes makes its appearance in induction furnaces; the liquid or semi-liquid charge draws itself at one place so as to narrow the section, and then an interruption occurs in the circuit with arcing, and the process is repeated.

Another advantage which the induction furnace possesses over the arc type is that the load is more constant and is under better control. In the case of direct-current arc furnaces the rapid variations in the load necessitate the use of special means to control the current.

We may next direct attention to a type of resistance furnace for smaller work in which the material creating the resistance is a granulated high-resistance mixture of carbon and other secret components, suitably named "kryptol." This granulated material is packed round a tube or crucible to be heated, and the current is sent through the kryptol by means of carbon electrodes. The substance

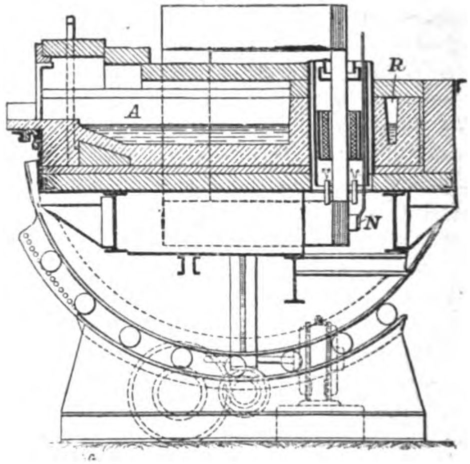

FIG. 30.—SECTION OF A TIPPING INDUCTION FURNACE.

which is to be heated is not therefore in contact with any material to injure it, and the operations take place just as if the tube or crucible were heated by gas. Such furnaces are more useful for chemical laboratory and small metallurgical work than for larger operations in the factory. To the same class belong the very useful laboratory electric furnaces introduced by Heræus. In these porcelain tubes of refractory material are wound outside spirally with platinum foil in strip, and the foil is covered with asbestos and refractory non-conducting material. If a current is passed through the platinum it can quickly be brought up to a temperature a little short of its melting-point (1,750° C.) and maintained for any length of time unaltered, say, at 1,500° C. Hence the interior of the tube can be raised to 1,400° C., or above the melting-point of gold and copper, in a very short time.

Such tubular Heræus furnaces are especially useful for conducting chemical organic combustions in glass tubes, and furnaces of this kind are made for heating crucibles, and also in the form of muffles for metallurgical research. They are supplied in London by Messrs. J. J. Griffin & Sons. The enormous advantage which they have over gas for these purposes is obvious. There are no products of combustion to defile the air and necessitate special means of ventilation, no

external radiation and waste of heat, and no chance of the products of combustion reaching and spoiling the substances under operation. No one who has carried out an organic combustion in a chemical laboratory with an Heræus furnace would ever desire to return even to the best of the gas furnaces used for this purpose. The electric furnace can, of course, be used in any position, and a tube can be heated vertically or at the top only, or in any limited position. Varieties of arc furnace for experimental work have been designed by Moissan, Borchers, and others. One common type consists of a pair of blocks of lime, fireclay or magnesia, hollowed out, so that when put together they form a cavity in which a substance can be exposed to the heat of an electric arc formed between two carbon rods, which are inserted through holes in the blocks and meet in the centre.

When the substance to be heated is not affected by contact with carbon at a high temperature, it may be placed in the hollow crater of the positive carbon, and then exposed to the highest temperature it is possible for us to obtain.

Where such contact with carbon is inadmissible, we can still obtain very high temperatures, exceeding 2,000° C., by passing strong electric currents through tubes of iridium or magnesia, within which the object to be heated is placed.

We have yet to consider the very simplest type of electric furnace, in which there is neither electric arc nor heating circuit, but the heat required is obtained by passing the current through the substance itself.

In nearly all cases the oxides or sulphides of metals are either very bad conductors or even non-conductors at ordinary temperatures; but these substances in most cases become conductors when heated. Whilst rise of temperature diminishes the conductivity of a metal, it increases that of the oxide of the metal. We have an excellent instance of this in the Nernst electric lamp. The oxide of magnesium or magnesia, as also the oxides of the rare metals thorium, yttrium, and so on, are practically non-conductors of electricity at ordinary temperatures. If, however, these oxides, or, better still, mixtures of them, are heated, they become fairly good conductors, and then can be maintained in an incandescent condition by a current sent through them. We have, therefore, only to overcome the initial stage of non-conductivity, and this can be done sometimes without prejudice to the results by mixing a certain proportion of graphite or coke with the oxide or substance. If, then, a current is passed, heat enough is produced by its passage through the carbon to raise the temperature of the mass to a point at which it begins to conduct all through, and the temperature can then be raised to any desired point by increasing the current.

The electric furnace is then reduced to its simplest elements—viz., the electrodes, which are generally carbon, and a mass of the substance operated on. We may even in many cases dispense with any containing vessel, the outer portions of the heap of stuff being heated being sufficient. In the next lecture we shall discuss several important industries which have grown up, based entirely on this simple mode of electrical heating.

On the present occasion I want to devote the remainder of the time to the discussion of some interesting questions with regard to the size and nature of the electrodes. With the exception of the induction furnace, we have in all cases to lead the current into and out of the object to be heated in the furnace by means of electrodes. These electrodes are not merely the avenues by which current or electric energy enters the furnace, they are also avenues by which heat escapes from it. A most important question therefore is the size and nature of these electrodes. Moreover the electrode, no matter what it may be, is a place in which the current is producing heat, and therefore the electrodes themselves dissipate electric energy. If anyone were asked what size the electrodes should be the first reply might be: as thick and short as possible, to avoid waste of electric energy in them. But this reply would have to be corrected, in view of the known fact that all good conductors of electricity are good conductors of heat, and therefore if the electrode is made a good conductor to avoid dissipating electric energy in it, it thereby becomes an easy avenue for the escape of heat from the furnace. Moreover, this escaping heat raises the temperature of the copper conductors conveying the current to the furnace, and thereby also increases the dissipation of energy in them. Hence the problem of the correct size of the electrodes is not to be solved without a careful analysis of the phenomena of the flow of heat and electricity in the electrodes. This analysis has been furnished by Mr. Carl Hering in an interesting series of papers which elucidate the matter admirably. Following him, let us consider the question of the dissipation and flow of energy in an electric furnace electrode or conductor which is insulated perfectly for

heat and electricity over its surface except at the ends. Let us suppose that this electrode is set in a furnace with one end kept at a temperature T (the hot end), and the other end (the cool end) kept at a temperature T_0. Let the length of the electrode be L and its section everywhere the same be S. Then consider a section at a distance x from the cool end, and let this section have a length dx. Let the temperature at the distance x be t, and that at the distance $x + dx$ be $t + dt$, then there is a gradient of temperature dt/dx down the section. Heat therefore flows from the hot end to the cool end of the electrode, and heat is also generated in the electrode by the current. Consider the section of length dx, then if A is the current and ρ the resistivity (taking the mean value), the heat, reckoned in joules, created per second in the section is equal to

$$\frac{A^2\rho\, dx}{S}.$$

Furthermore, heat flows through the section in virtue of the temperature gradient, and this heat, reckoned in joules, is equal to $JkS\frac{dt}{dx}$ where k is the thermal conductivity in calories per square centimetre per second per degree gradient. The heat that flows out of the section on the cool side being denoted by h, the heat that flows into it on the hot side must be less by the amount generated in the section electrically. Let us denote the heat flowing in by $h + dh$, and the heat flowing out by h, then the heat created in the section is

$$h - (h + dh) = -dh,$$

and this must be equal to

$$\frac{A^2\rho}{S}dx.$$

Also the heat flowing out is represented by

$$JkS\frac{dt}{dx}.$$

Accordingly we have

$$-dh = \frac{A^2\rho}{S}dx,$$

and integrating we have

$$-h = \frac{A^2\rho}{S}x + C$$

where C is some constant. Also

$$h = JkS\frac{dt}{dx},$$

hence

$$\frac{dt}{dx} = -\frac{A^2\rho}{JkS^2}x - \frac{C}{JkS}.$$

Integrating again we have

$$t = -\frac{A^2\rho}{JkS^2}\frac{x^2}{2} - \frac{Cx}{JkS} + C^1.$$

Now if $x = {}_0$, $t = T_0$, and hence $C^1 = T_0$. And f $x = L$, $t = T$, and we have

$$C = -\frac{1}{2}\frac{A^2\rho L}{S} - \frac{JkS}{L}(T - T_0).$$

Therefore

$$-h = \frac{A^2\rho}{S}x - \frac{1}{2}\frac{A^2\rho L}{S} - \frac{JkS}{L}(T - T_0).$$

This gives us an expression for the heat passing any section of the electrode per second at a distance x from the cool end. Let $x = 0$, then we have $h = H_0$, and therefore

$$H_0 = \frac{1}{2}\frac{A^2\rho L}{S} + \frac{JkS}{L}(T - T_0),$$

or the heat flowing out at the cool end is equal to the flux of heat due to conduction *plus* half the heat electrically produced in the electrode. If $x = L$, then $h = H$, and we have

$$H = \frac{JkS}{L}(T - T_0) - \frac{1}{2}\frac{A^2\rho L}{S}.$$

For electrodes of given material and for given temperatures of furnace, and given currents, these expressions may be written

$$H_0 = Pd + \frac{Q}{d},$$

$$H = \frac{Q}{d} - Pd,$$

where d is the dimension ratio L/S, and P and Q are constants.

Now it is clear that H_0 or the heat flowing out of the electrode is a function of d, the dimension ratio of the electrode, and H_0 is a minimum when d has such a value that $d = \sqrt{\frac{Q}{P}}$.

Also when this is the case H is zero or *no heat flows into the electrode from the furnace.*

Hence it is always possible to design electrodes for given cases which shall not rob the furnace of any heat or allow heat to pass through them from the furnace.

It will be seen that the ordinates of the curves denoting the variation of H and H_0 with d are the sum or difference of the ordinates of a straight line and an hyperbola, the slope of the straight line being $P = \frac{1}{2}A^2\rho$, and the constant of the hyperbola being $Q = Jk(T - T_0)$.

Hence the value of d or $\frac{L}{S}$, which gives the minimum heat loss, is given by

$$d = \frac{\sqrt{T - T_0}}{A}\cdot\sqrt{\frac{2Jk}{\rho}}.$$

For a given current and temperature fall it depends therefore only on the product of the thermal and the electric conductivity, and that substance will be the most useful for electrodes in which, other requirements being met, this

product is a minimum. Substituting the value of d, which makes the electrode loss a minimum, we find that this minimum loss from the cool end, which we will denote by H'_0, is given by

$$H'_0 = 2\sqrt{P}\sqrt{Q} = A\sqrt{2J}\sqrt{k\rho}\sqrt{T - T_0}.$$

This shows that when the electrodes have had their dimensions so proportioned as to produce the minimum heat loss from the cool ends, that minimum loss is proportional to the current, to the square root of the temperature gradients down them, and to the square root of the ratio of the thermal and electric conductivities. This ratio is very nearly the same for all pure metals, but not identical for non-metals, and for allotropic forms. It is also in pure metals proportional to the absolute temperature. The value of the ratio for carbon and graphite is not very certain, and we are ignorant of the manner in which these values vary with temperature.

In the above simple investigation Mr. Hering* has assumed that the quantities k and ρ are constant, and have values equal to the mean value between temperatures T and T_0. The necessary modifications, when k and ρ are taken as linear functions of temperature, have been made by Dr. A. E. Kennelly, and he has given the correct formulæ for the loss of heat at the cool end and absorption of heat at the hot end of the electrode.

Mr. Hering has made some measurements of the values of the ratio $k/K = k\rho$ for ordinary arc-light carbons and for graphite electrodes. He obtained the following values at about 900° C.

$$\text{Graphite } k/K = k\rho = 0{\cdot}74 \times 0{\cdot}000323 = 239 \times 10^{-6};$$

$$\text{Carbon } k/K = k\rho = 0{\cdot}329 \times 0{\cdot}00148 = 487 \times 10^{-6}.$$

Hence, at this temperature, 900° C., we should have as the values of $\sqrt{k\rho}$ and $\sqrt{k/\rho}$

$$\text{Graphite } \sqrt{k\rho} = 15{\cdot}5 \times 10^{-3}, \ \sqrt{k/\rho} = 48;$$

$$\text{Carbon } \sqrt{k\rho} = 22 \times 10^{-3}, \ \sqrt{k/\rho} = 15.$$

Accordingly, the minimum electrode loss for carbon would be 50 per cent. greater than for graphite. Also for a given length of electrode the graphite electrode could be one-third the section of the carbon. This investigation shows that the size of the electrodes is not a matter of indifference nor the nature of the material selected for them. For a given material it shows that there is a certain dimension ratio (L/S) which gives the minimum heat loss at the electrodes.

It proves also that the notion that graphite electrodes have a disadvantageous thermal conductivity is a fallacy, and it proves in addition that as far as nature of material is concerned that substance is the best for electrodes in which the product of the electric and thermal conductivities is greatest. The practical rule for electrode dimensions is, then, to make the electrodes as short as practical considerations will permit. As the appropriate cross-section will diminish with the length, this makes the bulk, and therefore the cost of the electrode as small as possible. Moreover, the equations show us the importance of producing the required furnace heat with as high a voltage and small a current as possible, and also effecting the required chemical change at the lowest possible temperature or avoiding excessive temperatures.

Much discussion has taken place on the validity of Hering's laws of electrode loss, but there is no doubt that the general principles on which they are based are sound. The modifications which have to be made in his equations when the variation of thermal and electric-resistivity with temperature is taken into consideration are not large, but the electrician who desires further details must be referred to the Papers published in the *Proceedings of the American Institute of Electrical Engineers for* 1909 *and* 1910, entitled "The Laws of Electrode Losses in Electric Furnaces," by C. Hering, "The Proportioning of Electrodes for Furnaces," by C. Hering, and the Paper by Dr. A. E. Kennelly already mentioned.

* See Dr. A. E. Kennelly, "On the Modifications in Hering's Laws of Furnace Electrodes introduced by including Variations in Electric and Thermal Resistivity."—*Proceedings of the American Institute of Electrical Engineers*, 1910.

A PROPOSED LOW-LEVEL TUNNEL AT MONT CENIS.

The advantage of a second tunnel, to relieve the heavy traffic on the Mont Cenis line, is a subject which is receiving considerable attention at the present time in France and Italy.

Opened on September 17th, 1871, the Mont Cenis tunnel was for ten years the only "gateway" by which railway travellers from western Europe could enter Italy. The opening of the two other great Alpine tunnels—viz., the St. Gothard in 1880, and the Simplon in 1906—have to some extent diverted the passenger traffic from the old capital of Piedmont.

The gradients on the approach to the tunnel from the Italian side are very steep, and it is thought that, by constructing a new tunnel at a

lower level than the present one, a considerable saving in the cost of traction could be made.

The new line, proposed by Signor D. Regis, a Turin engineer, would leave the present Turin to Modana railway at the station of St. Antonino, 35 kilometres (21¾ miles) from Turin, and follow the course of the Dora Riparia River on the right bank as far as the little village of Exilles. Here the valley would be crossed by a bridge and viaduct about 700 metres (765 yards) in length, to reach to the southern entrance to the great tunnel, a distance of 31 kilometres (19¼ miles), with gradients not exceeding 20 per 1,000 (1 in 50). The total rise from St. Antonino to this point is 523 metres (1,714 feet).

Piercing the mountain in a north-westerly direction for a length of 22,200 metres (13¾ miles), the tunnel would rise 154 metres (505 feet) to the culminating point, which is fixed at 1,069 metres (3,507 feet) above the sea-level. From this point, which is 226 metres (741 feet) below the greatest altitude in the Mont Cenis tunnel, there will be a fall of 12 metres (40 feet) to the northern entrance, situated about 450 yards from the existing frontier station of Modana, at an altitude of 1,057 metres (3,468 feet) above the sea-level.

The total length of the proposed line and tunnel would be 88½ kilometres, as compared with the 105 kilometres of the existing Mont Cenis route, a saving of about ten miles in favour of the former.

The cost of tunnel and approach line is estimated at 84 millions of lire (£3,360,000), and, if constructed, a saving of about 3,200,000 lire (£128,000) could be effected annually.

The following table gives the altitudes of the proposed tunnel (Exilles — Modana) as compared with those of the three existing Alpine tunnels:—

Name of Tunnel.	Length.		Height above Sea-level.		
	Metres.	Miles.	North Entrance.	Culminating Point.	South End.
			Metres.	Metres.	Metres.
Proposed low-level tunnel (Modana—Exilles)	22,200	13¾	1,057 (3,468 ft.)	1,069 (3,507 ft.)	904 (2,966 ft.)
Mont Cenis (Modana—Bardonnecchia)	12,133	7½	1,160 (3,805 ft.)	1,295 (4,248 ft.)	1,292 (4,239 ft.)
St. Gothard (Göschenen—Airolo)	14,920	9¼	1,109 (3,639 ft.)	1,154 (3,786 ft.)	1,145 (3,756 ft.)
Simplon (Brigue—Iselle)	19,734	12¼	687 (2,255 ft.)	705 (2,312 ft.)	657 (2,155 ft.)

THE SNUFF INDUSTRY OF BAVARIA.

It is in the mountain districts of Germany that snuff-taking is general, and it is in such districts that most of the forest areas of the country are found. In the forests, as a rule, smoking is forbidden, and this may account for snuff-taking superseding tobacco-smoking. A considerable portion of the Bavarian tobacco is made into snuff. There are several factories in Nuremberg that make a specialty of the so-called "Brazil-roll tobacco," made ready to be ground up for snuff, and in Landshut and Regensburg are half a dozen factories having a considerable output of an especially favoured brand of snuff known as "Schmalzler," undoubtedly so named because the main ingredient, after tobacco, is grease (Schmalz). Landshut is the centre of the Schmalzler snuff industry. It is still the custom for the old forest dwellers—that is, the Bavarian highlanders—to prepare their own snuff, which, in the language of the people, is known as "Schmei" or "Schmai," and almost every old snuff-taker has a special recipe of his own. According to the American Consul at Nuremberg, tobacco usually forms not more than half the body of this snuff. The tobacco is the so-called Brazil-rolls. These are formed of tobacco leaves first soaked in a syrup, strongly impregnated with various spices, and then twisted into hard rolls of about one inch and a half in thickness. These rolls can be bought from every village shopkeeper. The old snuff-taker adds to this tobacco, according to individual taste, beef tallow, a little lime, a small pinch of very fine pulverised glass, and such flavouring matter as his experience has found most pleasing. The ingredients are well mixed in a wooden bowl with a wooden pestle, the rubbing process being continued until the required degree of fineness is reached. Pine needles or other similar ingredients are often added as flavouring. The Schmalzler thus finished is usually carried in pouches made from hog's bladder, or in wooden boxes. According to statistics prepared at Passau, to which Landshut belongs, about 220,000 pounds of Schmalzler are consumed in the district annually. The production of the factories at Landshut and Regensburg is somewhat larger, but not very much, for the Schmalzler is largely consumed at home. As tobacco forms about half the bulk of the Schmalzler it follows that something over 110,000 pounds of tobacco are used by these factories annually. A good part of it actually comes from Brazil, where the roll bearing that name was first made, and these factories consume more than half the importation of this class of tobacco. In recent years, however, considerable quantities of Bavarian tobacco have been made into the so-called Brazil-rolls and eventually ground and mixed into the

Schmalzler. In the district about Landshut the habit of snuff-taking is almost universal. The children learn it early, and the women not infrequently contract the habit. Foresters sent there from districts where the habit is not known are said to acquire it very quickly, and its use and the strength of the habit have received official recognition in the instructions to the authorities of prisons and similar institutions in South Bavaria that confirmed snuff-takers must not be suddenly and entirely denied its indulgence.

THE WORLD'S PRODUCTION OF RAW SILK.

The *Union des Marchands de Soie* of Lyons, have published the following statistics respecting the production of raw silk throughout the world during 1910, as compared with that of the previous year:—

	1909 Kilogrammes.	1910
European Countries.		
France	674,000	320,000
Italy	4,251,000	3,947,000
Spain	82,000	83,000
Austria-Hungary	378,000	355,000
Totals	5,385,000	4,705,000
Levant and Central Asia.		
Turkey in Asia—		
Anatolia (Brussa and Ismid)	665,000	510,000
Syria and Cyprus	445,000	515,000
Other Provinces	125,000	100,000
Turkey in Europe—		
Salonica, Adrianople	380,000	285,000
Balkan States—		
Bulgaria, Servia, Roumania	223,000	170,000
Greece and Crete	60,000	55,000
Caucasus	540,000	520,000
Persia and Turkestan (exports)	600,000	540,000
Totals	3,038,000	2,695,000
The East.		
China (exports from Shanghai *)	5,185,000	5,345,000
China (exports from Canton †)	2,295,000	2,500,000
Japan (exports from Yokohama)	8,372,000	8,890,000
India (exports from Calcutta and Bombay)	235,000	215,000
Totals	16,087,000	16,950,000
General Summary.		
European Countries	5,385,000	4,705,000
Levant and Central Asia	3,038,000	2,695,000
Eastern Countries	16,087,000	16,950,000
Totals	24,510,000	24,350,000

* Including Tussah and native-spun silks.

† Including exports to Bombay and other parts of India.

These figures show a considerable falling off in the production of silk in Europe during 1910, as compared with that of the previous year. The decrease is particularly noticeable in France and Italy, in which countries the diseases of the silk-worm and mulberry tree are still so prevalent. On the other hand the East, particularly Japan, holds her own, and even shows a notable increase last year over the production of 1909.

NOTES ON BOOKS.

How to Manage a Suction Gas Producer. By W. A. Tookey. London: Percival Marshall & Co. 1s. net.

This little manual is designed for the use of engineers and attendants placed in charge of suction gas producers. It gives in simple language an account of the starting of a gas producer, the principles involved in gas production, the generator of a suction gas producing plant, the connections between the generator and scrubber, the scrubber and purifying apparatus, and the connections between the scrubber and the engine. A number of simple diagrams illustrate the text, and complete a very practical little handbook well calculated to fill the purpose for which it is intended.

Some Notes on the History of Secondary Education in Jamaica. By Frank Cundall, F.S.A. Kingston: The Institute of Jamaica.

Up to the middle of the nineteenth century the historian of secondary education in Jamaica had little to chronicle but mismanagement and misappropriation of funds; and even to a considerably later period the state of culture in the island appears to have remained somewhat elementary. Of late years, however, considerable improvements have been made. In most of the secondary schools the curriculum is now based on the requirements of the Cambridge University Examination Syndicate. This body has held examinations yearly in the island since 1882, when fifteen candidates sat. In 1898 and 1910 the total reached 328. In 1881 a stimulus was given to secondary education by the institution of the Jamaica scholarships (worth £200 per annum for three years, or £150 per annum for four years, or £120 per annum for five years), tenable at any recognised university or college in the Empire; and in 1904 the first Rhodes scholarship of £300 per annum, tenable at Oxford for three years, was awarded. This scholarship is limited every third year to candidates educated entirely in Jamaica.

The occasion which induced Mr. Cundall to put together these notes is interesting. They were prepared for the information of Mr. H. H. Piggott, H.M. Inspector of Schools, who in the beginning of this year visited Jamaica as a result of the suggestion of the English Board of Education that they

were willing to lend the services of an inspector for inspection work in any colony. Mr. Piggott's visit was the first of its kind paid by a British school inspector to a British colony.

GENERAL NOTES.

Pelagic Sealing.—The Pelagic Sealing Conference, which has been sitting at Washington, has come to the wise decision to suspend pelagic sealing for a period of fifteen years. The pelagic sealers kill the female seals on their way to and from the feeding grounds, and the death of every female so killed means the loss of two more lives to the herd—of the cub left to starve in the rookery, and of the cub as yet unborn. If this were continued, the total extinction of fur seals would soon be brought about. The herd has already been reduced from about two millions in 1882, when regular pelagic sealing began, to 185,000. It is to be hoped that the fifteen years' respite will do much to restore the herd to its former condition.

Forestry on American Railways.—The Pennsylvania Railroad has conducted forestry operations on a large scale for some years past, and according to the report of the company's forester, recently issued, some 4,000,000 trees have been planted in the last nine years, beginning in 1902 with 13,610, and reaching a maximum of 1,054,010 in 1909. The operations cover tracts of land adjacent to various points of the lines east of Pittsburg and Erie, and about thirty-two acres are devoted to nursery purposes at Morrisville, Pa. The company has recently completed two large sleeper and timber-treating plants at Mount Union and Greenwich Point, Pa., which have a combined annual capacity of 1,500,000 sleepers or their equivalent. Although this plant was not put in service until July 1st, 1910, the lumber treated during that year included 671,369 sleepers, 4,500,000 feet of lumber and switch timber, 90,306 paving blocks, and considerable quantities of fence-posts, cross-arms, and poles.

Mineral Production of the Island of Sardinia.—The mineral production of the Island of Sardinia during the year 1909 amounted to 168,481 tons, to the value of 18¼ millions of lire (£780,000). Of this amount zinc figures to the value of 9,200,000 lire (£368,000); lead, 5,400,000 lire (£216,000); lignite, 277,000 lire (£11,080); iron ore, 78,000 lire (£3,120); silver, 68,000 lire (£2,320); manganese, 470,000 lire (£18,800). These amounts, which are considerably below the average for the last ten years, are due to the low prices which have prevailed in the metal market for lead, zinc, and antimony. This has had the effect of stopping, to some extent, the exploration and development of mines throughout the island. The number of workmen employed in this industry was 12,487, being 1,238 less than the average for the preceding nine years.

The Hemp or "Chingma" Industry in China.—Chingma, which means a light-green hemp, is cultivated to a considerable extent in the Tientsin district, in the Pei-ho Valley, along the Grand Canal, and in the region to the north and west of Pekin. The methods of preparing the fibre for market are very primitive. The leaves are stripped from the stalks by hand, and are used for a number of purposes. The fibre is contained in the outer rind or bark of the stalk, as is the case with flax, and is submitted to a process analogous to the retting of flax. The stalks, bound in bundles, are submerged in water, generally in a stagnant pool, and mud from the bottom is piled over them to keep them covered. After time has elapsed to allow the vegetable gum which holds the fibres together, and to the inner stalk, to decay, the stalks are stripped of the fibre by the latter being drawn by hand over the teeth of a rude iron comb, fixed to a heavy plank. This combing is all the preparation it gets. It is then made up into bundles for the market. The inner stalks, which are very white, are used for fuel. Large quantities of the fibre are exported from Tientsin.

Electrolytic Steel.—The manufacture of electrolytic steel seems to be progressing in Norway. Two new companies have just been formed, and made a beginning with building operations. The Stavanger Staalverk Aktieselskab has a capital of 450,000 kronen, and has entered into an agreement with one of the power companies to take 2,500 horse-power annually, the price fixed being between 20 kronen and 25 kronen per horse-power year. The intention is to erect one electric furnace, a rolling and hammering plant, and a foundry, the productive capacity being 1,400 tons of rolled steel, 300 tons of hammered steel, 600 tons of cast steel, and 700 tons of waste. The second works is being erected by a small company formed in 1896, the capital being increased to 2,200,000 kronen. Electric power is to be got from Böilefos Falls, Nidelven, and a steel plant is to be built near Arendal. As with the Stavanger Company, the electric furnace to be employed is that of the Swedish Electrometal Company. The estimated output is 14,500 tons annually.

Decrease of Horses.—According to the returns issued by the Board of Agriculture for 1910, the total number of horses in Great Britain used for agricultural purposes (including mares kept for breeding and unbroken horses) was 1,545,376, or 7,617 fewer than in 1909. The total number of cattle of all kinds returned in 1910 was 7,037,327. Since 1905, when the number of horses reached 1,572,433, there has been a steady decrease at the rate of 13,000 a year. In the census years of 1871 and 1881 there were on the farms of Great Britain 48 horses for every 1,000 of population. In 1891 the number was 45, 41 in 1901, while in 1910 the proportion of horses was only 38 to every 1,000 of the estimated population.

Journal of the Royal Society of Arts.

No. 3,061. VOL. LIX.

FRIDAY, JULY 21, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

PRESENTATION OF THE SOCIETY'S ALBERT MEDAL TO THE HON. SIR CHARLES PARSONS.

The Council of the Royal Society of Arts attended at Clarence House on Friday, the 14th inst., when His Royal Highness the Duke of Connaught, K.G., President of the Society, presented its Albert Medal to the Hon. Sir Charles Algernon Parsons, K.C.B., LL.D., D.Sc., F.R.S., "for his experimental researches into the laws governing the efficient action of steam in engines of the turbine type, and for his invention of the re-action type of steam turbine and its practical application to the generation of electricity and other purposes."

The members of the Council present were :—Lord Sanderson, G.C.B. (Chairman), George Ranken Askwith, C.B., K.C., Sir Steuart Colvin Bayley, G.C.S.I., C.I.E., Sir George Birdwood, K.C.I.E., C.S.I., M.D., LL.D., Henry Taylor Bovey, LL.D., F.R.S., Lord Blyth, Dugald Clerk, F.R.S., Alan Summerly Cole, C.B., Hon. Sir Charles W. Fremantle, K.C.B., Robert Kaye Gray, Colonel Sir Thomas H. Holdich, R.E., K.C.M.G., K.C.I.E., Sir John Cameron Lamb, C.B., C.M.G., Sir William Lee-Warner, G.C.S.I., William Henry Maw, M.Inst.C.E., Hon. Richard Clere Parsons, M.A., Sir Westby B. Perceval, K.C.M.G., Sir Boverton Redwood, Bart., D.Sc., F.R.S.E., Sir Owen Roberts, M.A., D.C.L., Carmichael Thomas, Sir Philip Watts, K.C.B., LL.D., D.Sc., F.R.S., Colonel Sir John Smith Young, C.V.O., with Sir Henry Trueman Wood, M.A. (Secretary), and G. K. Menzies, M.A. (Assistant Secretary).

SHIPLEY'S TOMB.

It was mentioned in the Annual Report* that the Council had defrayed the cost of renovating the tombstone of William Shipley, the originator of the Society, who died at Maidstone in 1803, and was buried in All Saints' Churchyard there. Mr. J. H. Allchin, the Curator of the Maidstone Museum, has kindly furnished the Secretary with a transcript of the inscription on the stone, which was formerly illegible. It reads as follows :

To the Memory of
WILLIAM SHIPLEY ESQ.
late of this Town,
whose Public Spirit
gave rise to the Society
established in London,
for the Encouragement
of Arts, Manufactures,
and Commerce,
Ob[t] 28[th] December
1803, Æt. 89.
Also of M[rs] ELIZ[th] SHIPLEY,
his widow,
Ob[t] 13[th] August
1806, Æt. 76.

On the south side of the tomb is the following inscription :

ELIZABETH SHIPLEY,
died March the 8[th] 1769,
Aged 2 Months.

It may be noted that the inscription does not absolutely settle the doubt referred to in the *Journal* of June 9th (p. 769, footnote), as to the precise date of Shipley's birth, though it appears to make it certain that he was born either in 1714 (the accepted date, perhaps taken from the tombstone), or in 1715 (which appears more probable). *Ætate* is a little vague, and might equally well be used of a man who was over 89, or in his 89th year.

* See *Journal*, Vol. LIX., p. 823, June 30th, 1911.

PRACTICAL EXAMINATIONS IN MUSIC.

The Practical Examinations in Music were not concluded this year until the 10th inst., too late for the results to be included in the Report of the Council. They lasted for seven days.

The examinations were conducted by Dr. Ernest Walker, M.A., and Mr. Burnham Horner.

The system of examination was the same as that for recent years. For instrumental music certain standards are given, and candidates are asked to select for themselves which of these standards they choose to be examined in. The standards range from easy to very difficult music. For each standard a list of music is given for study, and from this list candidates select the pieces they will sing or play. Candidates are expected to play or sing the pieces which they have prepared, to play or sing a piece, or portion of a piece, at sight, and to play certain scales.

In all, 289 candidates entered, and of these 283 were examined, a decrease of 56 as compared with last year. There were 214 passes and 69 failures.

The following were the subjects taken up:— Piano, singing, violin and violoncello. 239 entered for the piano, 182 of whom passed; 37 entered for the violin, of whom 28 passed; 4 entered for the violoncello, 3 of whom passed; 8 entered for singing, of whom only 1 passed. One medal was awarded.

The quality of the competitors was, on the whole, much the same as usual, though that of the junior pianists was perhaps slightly better than last year. A good many failed through attempting standards too high for their present attainments; and there were often signs, among the pianists, of insufficient attention to details of touch and phrasing. The best work was among the violinists, some of whom showed great promise.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

THE APPLICATIONS OF ELECTRIC HEATING.

By Professor J. A. Fleming, M.A., D.Sc., F.R.S., M.Inst.E.E.,

Pender Professor of Electrical Engineering in the University of London.

Lecture III.—Delivered March 20th, 1911.

The Technical Applications of Electric Heating.

We shall, in the present lecture, consider some of the most important of the technical applications of electric heating and products of electric furnaces. There are whole manufactures which have been entirely created of late years by the possibilities of electric heating, and other fields in which it is proving a valuable auxiliary to ordinary combustion heating. Let us discuss first some of the cases in which resistance-heating is employed in its simplest form—viz., in which the material to be operated upon is itself the resistance by which the heat is produced. One of the most striking of these is the manufacture of *carborundum*, which has attained considerable proportions in the United States at Niagara Falls.

Carborundum is a carbide of silicon produced by heating sand, sawdust, and coke to a temperature of 1,950° C., or near the melting point of iridium. At that temperature a reaction takes place in accordance with the chemical equation:

$$Si\,O_2 + 3\,C = 2\,CO + Si\,C.$$

At a higher temperature still, about 2,250° C., the carbide of silicon is dissociated and the carbon deposited in the form of graphite. Carborundum so made presents itself in bluish crystals having a specific gravity of 3·12 and a hardness approaching that of the diamond. This substance was produced first by Mr. E. G. Acheson in 1891, during an attempt to make diamonds artificially. It is now manufactured at the rate of 3,000 tons or more a year at Niagara Falls by currents generated in the Falls power-house. Owing to its great hardness it is found to be an excellent substitute for emery, and is enormously used in the production of grinding-wheels of all kinds and polishing powders. A small but interesting use of it is as a receiver in wireless telegraphy, owing to the unilateral conductivity possessed by the crystal. It is made by passing a powerful current through a mass of finely-powdered coke sawdust and sand in proper proportions. This mixture is stacked in rectangular furnaces built

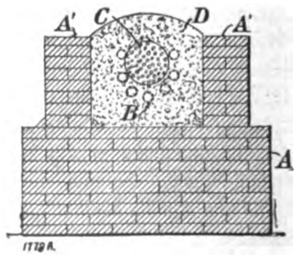

Fig. 31.—Section of Acheson Carborundum Furnace, showing the Coke Core, C, and Charge, D.

of loose bricks about 16 × 7 × 6 feet in size, through the ends of which massive electrodes of carbon are thrust to convey the heating current into the mass. A core of granulated coke is laid along the centre from electrode to electrode to start the heating (see Fig. 31).

The current through the mass increases as the temperature rises, and finally remains steady at about 7,500 amperes when supplied at 100 volts, the power taken being therefore 1,000 h.-p.

The carbonic oxide produced by the reaction escapes through the bricks, and is allowed to burn on the outside. The process of cooking a charge takes twenty-four hours, at the end of which time the structure is dismantled and the contents sorted out. The 1,000 h.-p. furnace yields about four tons of carborundum per diem, and there is also a by-product of graphite from the coke core. The carborundum works at Niagara produce about seven to ten tons per day, using 3,000 h.-p., delivered as electric current from Niagara Falls.

Closely connected with this is another large manufacture started by Mr. Acheson, in which *graphite* is prepared in various forms from coke and coal. Graphite, also called plumbago or blacklead, is one of the allotropic forms of carbon, and both the other varieties of carbon—viz., diamond and charcoal—are converted into graphite at a high temperature. Graphite is characterised by a higher electric conductivity, by marking paper, and by resistance to ordinary chemical reagents. Hence, it has enormous uses in the manufacture of electrodes for electric furnaces, crucibles and other things. Moreover, owing to its smooth, greasy nature, it is largely used as a lubricant in various forms. It occurs native as plumbago, in which form it is used for making lead pencils, but many mines are now becoming exhausted. Acheson devised a process of making it electrically from anthracite coal. This coal is powdered and stacked in a rectangular brick furnace similar to those used in carborundum manufacture (see Fig. 32). A core of coke is built in connecting the

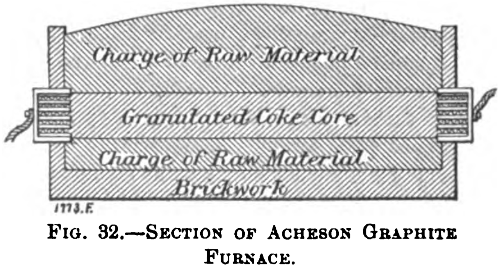

Fig. 32.—Section of Acheson Graphite Furnace.

massive carbon electrodes and the current is then turned on. The process of conversion is not simply a thermal one, but the silica in the coal probably plays an important part, a carbide of silicon (carborundum) being first formed in the interior and then broken up at a higher temperature with deposition of the carbon as graphite as the temperature rises. In this manner the same silicon is used over and over again, as it makes its way from within outwards. The result is that the coal is finally transformed into graphite. Over 2,000 tons per annum are now produced at the Acheson graphite works at Niagara Falls. Acheson has recently discovered methods for producing not only a hard form of graphite for electrodes, but soft oleaginous graphite with which a whole series of oily lubricants are manufactured.

In connection with the above manufactures, which are carried on at Niagara Falls, mention should be made of aluminium production, for though this is partly an electrolytic operation, yet electric resistance heating enters into the process. The problem of profitably extracting metallic aluminium from the earth's strata, which contain it, was for long an unsolved enigma. Oxide of aluminium or alumina forms a large part, some 17 to 20 per cent. of the sedimentary terrestrial crust, but the oxygen is so firmly held by the aluminium that it cannot be reduced by heating with carbon, as is the case with oxides of the most common metals. After several processes had been tried and abandoned, the practical solution was arrived at almost simultaneously in America and in France by two young chemists—Hall and Héroult—when both were hardly more than students. It is as follows:—The mineral cryolite is a double fluoride of aluminium and sodium, and is fusible at a good red heat. The substance called fluorspar, or blue john, is a fluoride of calcium, and is also fusible. If the cryolite and fluorspar are mixed in certain proportions and melted, the liquid will dissolve alumina. The alumina used in manufacture is prepared from Irish bauxite, which is a crude oxide of aluminium, containing also silicates and iron. The hydrated alumina is extracted from the bauxite and rendered anhydrous. A mixture of cryolite, fluorspar and pure anhydrous alumina is then placed in an iron crucible lined with carbon and heated. When fluid a graphite electrode is dipped into it and a current sent through the fluid, which heats it and keeps it liquid (see Fig. 33). Also if the graphite is the anode, the liquid is electrolysed and metallic aluminium is deposited at the bottom of the crucible. The success of the process depends on the fact that the reduced aluminium has a greater density than the fused salts, and hence falls to the bottom of the pot, and is drawn off at

intervals by a tap. The process is continuous. If the voltage per pot does not exceed five or six volts the alumina alone is electrolysed and not the cryolite or fluorspar. Hence it is only necessary to add fresh alumina from time to time, and to draw off the deposited aluminium. Of the energy of the current about half is absorbed in keeping the contents of the crucible liquid—viz., at 850°–900° C., and the remainder in effecting the reduction of the oxide.

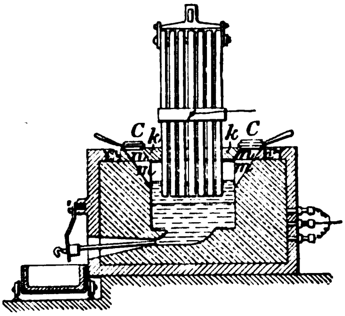

FIG. 33.—SECTION OF ALUMINA REDUCTION POT.

This Hall-Héroult process is now carried out on a large scale at Niagara Falls, U.S.A., at Neuhausen, on the Falls of the Rhine in Switzerland, and at the Falls of the Foyers on Loch Ness, and at Loch Leven in Scotland, by the British Aluminium Company, where 30,000 h.-p. are being so used. The electric current required is generated by dynamos driven by water-turbines by the falls, and is led through a number of the electrolytic pots in series. Each pot takes a current of about 7,000 to 10,000 amperes at five volts or 50 k.w., and the number of pots worked in series depends on the electromotive force of the current. At Niagara Falls each pot takes up 65 h.-p., and produces 112 lb. of aluminium per day.

As an illustration of the enormous development of the industry, Mr. Kershaw mentions, in his excellent book on electro-metallurgy that in 1886 the total production of aluminium in the world was only three tons and the price £2 16*s.* per lb. In 1906 it had risen to 12,000 tons, and the price had fallen to 1*s.* 10*d.* per lb. The total cost of production of aluminium by this Hall-Héroult process is about 1*s.* per lb., but not an inconsiderable fraction is the cost of the preliminary preparation of the pure alumina. The possibility of cheapening the production of aluminium depends almost entirely on improvements in cheapening the production of the pure anhydrous alumina, or else in using the crude bauxite itself directly in the furnace. It is needless to refer to the ever-increasing uses of aluminium in the arts. It has become a rival to copper as an electric conductor, and in combination with other metals furnishes alloys of great utility.

As a final example of this mode of electric resistance heating the manufacture of calcium carbide may be mentioned. Calcium carbide, $Ca\,C_2$, is a compound of calcium and carbon, which is prepared by heating lime and coke intensely in an electric furnace. Potassium carbide was first produced by Sir H. Davy in 1808, and calcium carbide by his cousin, Robert Davy, in 1836, and re-discovered by Wöhler in 1862, and again by Moissan and Willson in 1892. The reaction which takes place is represented by the equation

$$Ca\,O + 3\,C = Ca\,C_2 + CO.$$

When calcium carbide is acted upon by water the inflammable gas acetylene is produced

$$Ca\,C_2 + 2\,H_2\,O = Ca\,H_2\,O_2 + C_2\,H_2.$$

Acetylene is now much used for the production of lighting gas. More recently calcium carbide has found another field of work in the preparation of calcium cyanamide, now used as a fertiliser. The manufacture of calcium carbide is conducted on a large scale at Odda, in Norway, where 23,000 h.-p. are taken from the River Tysse, and partly thus used for the preparation of nitrate fertilisers. The calcium carbide is crushed, and nitrogen gas prepared from liquid air is passed over the carbide at a high temperature. The two substances combine with the production of calcium cyanamide. This material is used as a fertiliser, and when placed in the soil and acted on by water, supplies the nitrogen necessary for the growth of vegetable food-stuffs in the form of ammonia.

During last year the total production of calcium carbide in the whole world for acetylene gas production amounted to nearly 240,000 tons, whilst some 15,000 tons were used for the production of cyanamide. At Odda about 20,000 tons of carbide were made for lighting purposes and about 4,000 for the manufacture of cyanamide. In fact, we may say that the manufacture of calcium carbide is one of the most important of the electro-thermal industries at the present moment.

Before leaving, however, the discussion of those manufactures which involve pure resistance heating, we may refer to the application of electric heating, of increasing importance in connection with the manufacture of ordinary and of quartz glass. Ordinary glass is a mixture of silicates of various bases—soda, lime and

oxide of lead, and the materials are heated in a furnace to the melting-point generally by producer gas. The glass so made softens at or below a red heat, and owing to its relatively large expansion with rise of temperature is easily cracked if heated unequally. The application of electric heating to ordinary glass-making has not yet made great advance, owing chiefly to the great economy of the regenerative gas furnace, but for special kinds of glass it is found that advantage is gained by heating the pots by packing them round with kryptol, through which a current is sent. An entirely new manufacture has been developed of late years in the production of pure quartz glass. Quartz is nearly pure silica, but melts only at a temperature of 1,800° C. to 2,000° C. Moreover, quartz has a very small coefficient of expansion, and a quartz article can be heated red hot and plunged into water without cracking.

A mass of homogeneous quartz can be prepared by a process due to Messrs. Day and Shepherd. Fragments of quartz are placed in a thin-walled graphite box, which is included in an air-tight steel vessel. The graphite box is heated electrically up to a temperature of about 2,000° by passing a current through it. The quartz is melted and partly volatilised. The air is displaced from between the fragments, a considerable air pressure, 500 lb. per square inch, is then applied, and the temperature of the quartz kept at 1,800° C. for some time. On cooling the quartz fragments are found to have become a homogeneous mass. Quartz can be worked like glass in the oxyhydrogen blowpipe and fused electrically, and chemical vessels of all kinds are now made with it, which have great advantages over glass.

A very striking example of the utility and importance of electrical heating is to be found in the comparatively modern industry of producing ferro-alloys. Of late years metallurgists have discovered the great effect which small percentages of chromium, nickel, manganese, vanadium and tungsten, either separately or together, produce on the physical properties of iron and steel, and the preparation of alloys of iron with these metals as well as with non-metals, such as silicon, is now a prosperous manufacture, carried on chiefly in France, Germany, and America.

Metallurgists distinguish steels as binary, ternary, quartenary, according as they contain two, three, four, etc., elements. Ordinary steel is a binary, and consists of an alloy of iron with certain carbides of iron. If, however, a small proportion of chromium, vanadium, tungsten, or nickel is added to the molten steel before casting, the resulting properties of the metal are quite different from those of ordinary carbon steel. Very striking results as to tensile strength, hardness, and resistance to shock are obtained from low carbon quarternary steels containing these metals, and these steels are much used for motor-car axles, for armour-piercing projectiles, for high-speed tools for metal turning, and numerous other purposes. As the amount of the third or fourth element is extremely small, 1 or 2 per cent., or less, and must be uniformly diffused, it is found it can best be imparted by putting into the carbon-steel, when in a molten condition, a certain proportion of an alloy of iron having in it a large known percentage of the special metal.

The manufacture of these ferro-alloys is now carried on at places where water-power is abundant and available for the production of electric current for use in electric furnaces.

One of the largest of these is in France, in the Haute Savoie, where the Girod Electrometallurgical Company is using 18,000 h.-p. for the production of ferro-silicon, ferro-tungsten, ferro-molybdenum and ferro-vanadium, the output being 9,000 to 10,000 tons per annum, valued at £360,000. The type of electric furnace in which these alloys are prepared is illustrated by the views shown of the Girod, Héroult and Keller electric furnaces.

One of the alloys most in demand is ferro-silicon, an alloy of iron with 10, 20, 50, or 80 per cent. of silicon. This alloy is used to bestow hardness and fluidity in cast-iron, by adding a certain proportion of it to the molten iron just before casting; 5,000 or 6,000 tons of it are produced per annum at the Girod works alone.

Another important alloy is ferro-tungsten. It is employed in the production of high-speed tool steel, which does not soften even at a red heat, and can, therefore, be used for making cutting tools, which cut much faster than ordinary carbon-steel and effect an enormous saving of time in engineering shops. The demand for this steel has greatly increased since 1900, when the Bethlehem Steel Company's exhibit at the Paris Exhibition drew attention to this subject. Over one half of the ferro-tungsten made is used in Sheffield.

The manufacture of these ferro-alloys is at present being conducted in France by MM. Keller, Leleux et Cie, at Livet and at Kerrousse, and also by the French Electro-

metallurgical Company, at La Praz and St. Michel, and, as already mentioned, by the Girod Electrometallurgical Company at Ugine. In Colorado, U.S.A., a large works has recently been erected for the production of ferro-vanadium.

At Livet and Kerrousse the Keller electric furnace is employed. The materials for making the alloys, iron or steel, scrap ores or oxides of the special metals, coke and fluxes, are charged into the towers and then heated by a very strong current. The heat is produced partly by resistance and partly by arc. The liquid alloy collects in the lateral channel of the furnace, and is tapped off at intervals. At La Praz and St. Michel the Héroult arc furnace is employed, and at Ugine the Girod furnace. There is a great demand for ferro-silicon containing various large percentages of silicon for use as a deoxidising agent. Ferro-chrome is largely used in armour-plate manufacture to bestow hardness, whilst ferro-vanadium has been found of the greatest use in bestowing power of withstanding shock in steels employed in axles, shafts, and gears of motor-cars. At first difficulty was experienced in obtaining ferro-alloys sufficiently free from carbon, but by the use of pure raw materials, avoiding over-heating, and by the prevention of contact between the electrodes and the charge, or by the use of induction furnaces, these difficulties have been overcome, and the carbon contents have now been reduced to about 2 per cent. It is for this reason that resistance or induction furnaces are most advantageous in the preparation of ferro-alloys.

As regards the products of these factories, they are chiefly ferro-chrome for hardening steel, ferro-tungsten for producing high-speed steel, ferro-silicon for general foundry work.

Steels containing from 7 to 22 per cent. of chromium are very hard and resist shock, whilst a small addition of vanadium, 0·2 to 0·8 per cent., gives great toughness as well and ability to withstand vibration. Another alloy steel which has a high value is molybdenum-chromium-steel, employed in making armour-piercing shells, on account of its great hardness and toughness. The special qualities of these steels will, however, be best discussed after describing their mode of preparation. The application of the electric furnace in the manufacture of iron and steel has opened a new chapter in the history of one of the leading industries of the world.

For the sake of those who are not metallurgists it may be well to sketch in outline the older processes for the production of iron and steel, in order that the novelty introduced by electric heating may be better understood. Iron occurs in nature in the form of impure oxides or carbonates. The purest ore is *magnetite*, or magnetic oxide of iron (Fe_3O_4), which is widely distributed in the earth's crust. Much of the best Swedish iron is made from this ore. Magnetite contains about 70 per cent. of pure iron.

The ore known as *hæmatite*, red or brown, is a ferric oxide, anhydrous or hydrated, but the chief source of iron in Great Britain is the abundant clay ironstone, which is an impure ferrous carbonate containing 30 to 33 per cent. of pure iron and found with the coal measures in Staffordshire, South Wales, and likewise in places in Central Europe.

The preparation of iron from the clay ironstone involves the following processes. The ore is broken up and roasted to expel water and carbonic dioxide and leaves a crude oxide of iron as the result, mingled with silica, aluminic silicates and magnesia and oxide of manganese, also some phosphates. The ore is then treated in the blast furnace, being heated in a blast of hot air when mixed with coke and lime. Pure iron is only fusible at about 1,500° C., but if carbon is present, then the melting-point, in accordance with the usual rule, is lowered. Molten iron also dissolves carbon very readily. Accordingly the process of reducing the iron ore consists in heating it with carbon in the form of coke. The carbon combines with the oxygen, forming carbonic oxide and dioxide, and with the iron forming a carbide of iron, whilst carbon is also dissolved by it as well. The lime is necessary to act as a flux, and it combines with the silica and alumina to form an easily fusible slag. The lime also removes sulphur and phosphorus to some extent. The carbon in the resulting metal varies from 3½ to 6 per cent. The product of the blast furnace when run off into moulds is known as cast-iron or pig-iron. There are three varieties of it called respectively, *grey*, *mottled* and *white* cast-iron. The white cast-iron contains the same percentage of carbon as the grey or mottled, but the greater part of it appears to be chemically combined with the iron, whereas in the other two uncombined carbon is distributed throughout the mass. The grey cast-iron is preferred for casting, and is that variety produced when the blast furnace is in good working order. To obtain the very high temperature required for the reduction of

the ore a large quantity of air has to be forced through the blast furnace, but by the regenerative methods now in use the heat from these escaping gases is utilised to heat the incoming blast.

It has been found possible to produce 1 ton of pig-iron by the use of 16 cwt. of coke, but as 6·5 cwt. out of this are required to reduce the oxide to the metallic state, only 9·5 cwt. are used to produce the high temperature. The problem of producing pig-iron from ore electrically is, therefore, reduced to the possibility of heating a mass of iron ore, lime, and coke to the required temperature by the passage of a current to bring about the above-described reduction. This can be done in the Keller and other forms of electric furnace, but unless the electrical power can be obtained extremely cheaply, or unless the price of coal is very high, the electrical production of pig-iron does not seem able yet to compete with the combustion process. Hundreds of tons of pig-iron have, however, been prepared in the Keller furnace electrically. To produce 2,000 lbs. of pig-iron from ore charged cold into the electric furnace appears from experience at Niagara Falls to require 2,500 kilowatt-hours of electrical energy. If the ore is heated first the expenditure can be reduced to 2,000 kilowatt-hours. Even if we take the cost of the kilowatt-hour as low as ¼*d.*, it is clear that the electric-power cost will be £2 1*s.* 8*d.* per 2,000 lbs. of pig, which is in excess of the cost of the 10 cwt. of coke which could be saved, taking prices which rule in Great Britain and many other countries.

Cast-iron or pig-iron may be regarded as the raw material for the production of iron in the forms in which it is required in modern engineering. The excess of carbon, especially the uncombined carbon, in the pig gives it brittleness and want of tensile strength, which render it unfit for many purposes. This excess can, however, be removed, and gives us the material in the form of wrought-iron or steel. It would occupy far too much time to enter into a full discussion of the constitution of the iron-carbon compounds. Suffice it to say that wrought-iron is, or should be, nearly pure iron with very small admixture of carbon, sulphur, phosphorus, silicon and manganese, the iron amounting to 99 per cent. or over. It has a fibrous structure, is soft, and can be welded, and has a high melting point, near 1,500° C. The substance known as carbon-steel consists of a solid admixture or alloy of a carbide of iron with iron. This carbide has the composition Fe_3C, and is called *cementite*, the pure iron being known as *ferrite*. The amount of carbon may vary from 0·3 to 1·57 per cent., according to the mode of production. Steel may in a sense, therefore, be said to be the connecting link between wrought-iron or pure iron and cast-iron. Steel, however, differs strikingly from wrought or cast-iron, in that many grades of it can be hardened by quenching suddenly when at a high temperature. It then becomes so hard that it will scratch glass. If the hard steel is heated to a certain point, and slowly cooled or annealed, it becomes elastic. In annealed steel the carbide of iron appears to be distributed throughout the mass in little aggregations. If, however, the steel is heated, this carbide is dissolved, and becomes diffused through the iron. Quenching or cooling suddenly prevents the carbide from aggregating itself, and the solid uniform admixture of carbide of iron in iron is extremely hard. The hardness of steel is a result, therefore, of the formation in it of more or less of this constituent. If the steel is then slowly heated again after quenching, the constituents undergo rearrangement and the separation of the carbide, or its aggregation, again takes place, and is accompanied by a softening of the metal as the martensite disappears. It is this property of possessing a large range of hardness, combined with its elasticity and tensile strength, which gives steel its engineering value. Hence the production of steel consists in giving to, or leaving in, the iron just enough carbon to form the requisite quantity of active carbide without any excess. Steel can, therefore, be made in a variety of ways. It may be done by adding the proper quantity of carbon to pure or wrought-iron; or it can be made by taking away from cast-iron a part of the carbon. Steel can also be made directly from pure oxides of iron or ore. In carrying out the first method pig-iron, as made in the blast furnace, is first refined by melting it and exposing it to a current of air by which it is partly oxidised, and this oxide of iron then gives up oxygen to the carbon in the form of carbonic oxide, which escapes from the molten mass. If oxide of iron in the form of iron scale is added and the mass stirred in proportion as the carbon is oxidised, this mass becomes less fusible. It is finally withdrawn from the puddling furnace, and by hammering and rolling compressed into bars of so-called wrought or worked iron. To convert it into steel, carbon must be imparted to it in certain proportions. This was formerly done by heating

the iron bars with carbon in a furnace for several weeks. The process called cementation converted the iron into steel, at least on the outer portions. A more homogeneous material was then obtained by melting these steel bars in a crucible and casting it in the form of *cast steel.* Bessemer invented the process of depriving cast-iron of its carbon by blowing air through it, and then adding to the deoxidised iron just enough carbon in the form of a highly carburetted iron to convert it into steel.

Since steel presents us with a wide range of properties in the finished material, and with greater toughness and less brittleness than cast-iron, and greater tenacity and less plasticity than wrought-iron, practically the whole of the iron required in engineering is required or used in the form of steel. The great problem of iron metallurgy is therefore the production of steel in the various qualities required for engineering work. Again, since the discovery of the enormous influence of small amounts of special metals on the qualities of the resulting steel, the manufacture of ternary and quarternary steel has assumed a most important aspect.

The problem before the iron and steel manufacturer in England is to produce as quickly and cheaply as possible a material from our British iron ores which can be converted into steel. Owing to the proximity of the clay ironstone deposits to the coal measures in Great Britain, and to the exhaustive attention which has been given to the theory and practice of the blast furnace, the possibilities for employing electric heating in the manufacture of pig or cast-iron are not large, since the margin for economy is very small. In countries where coal is dear and water-power abundant, the case is different, and the electric production of pig-iron may have a future. On the other hand, it has now been recognised that in the production of steel, and especially of high-grade compound steels, the electric furnace is destined to play a most important part in the present and future of steel manufacture. In making steel the crude cast-iron has not only to be deprived of the excess of carbon, but also of sulphur and phosphorus, and the silicon and manganese reduced below certain values. Also the steel has to be prevented from taking up and occluding gases. It is well known that most bars of steel when put into a vacuum give out nitrogen, which has been absorbed in the manufacture.

In the ordinary furnace processes of making steel in the Siemens-Martin open-hearth furnaces the steel is exposed to the products of combustion. If there is an excess of air—that is, if the flame is kept in an oxidising state—there is unnecessary loss of iron, and it is impossible to free the steel from absorbed gases. On the other hand, if the flame is kept reducing it is difficult to obtain a high enough temperature. These difficulties are overcome by electric heating. The temperature can be raised to a sufficiently high value to get rid of occluded gases. The carbon can be removed by the addition of iron oxide, and the metal can also be freed almost completely from the sulphur and phosphorus by appropriate fluxes.

The electric furnace is well adapted therefore for the manufacture of case-hardening steels as the action of air can be avoided and a sound homogeneous metal obtained without excessive additions of silicon and manganese.

At the present time the great use of the electric furnace is in the production of steel direct from pig-iron and scrap. The process when using an arc-resistance furnace of the Héroult or Girod type is as follows:—

A charge of pig-iron and scrap-iron is laid on the hearth and iron ore (oxide of iron) and lime added in calculated amount to produce a slag. The current is then turned on and the charge melted by combined arc and resistance heating, and the melted slag then prevents further oxidation. The decarbonisation of the iron and its purification from sulphur and phosphorus is then assisted by turning on an air-blast, as in the case of a Bessemer converter. When the iron is sufficiently refined a known and calculated amount of carbon is added in the form of a carburite or highly-carbonised iron, and the resulting steel is tipped into the casting ladle. According to details given by Mr. J. B. C. Kershaw (see *Electrometallurgy*), one Héroult furnace at La Praz produces six tons of steel per day in two heats of three tons each, using 4,000 amperes at 120 volts. The resulting product contains only ·003 per cent. of phosphorus and ·007 per cent. of sulphur, whilst the carbon and silicon can be varied at pleasure by adding carburite or ferro-silicon at the end of the operation. Single electric furnaces are now, however, in operation turning out 200 tons of steel per day for the last sixteen months. In the electric furnace almost any degree of refining can be carried out, as the sulphur and phosphorus can be almost completely removed and the quality of the electric-made steel is better than that of material of similar composition made in an oxidising furnace. It appears that scrap-iron can be economically

refined and converted into good steel by the expenditure of about 700 to 800 kilowatt-hours, or kelvins, per ton in a Héroult furnace.

In the case of special steels in which various ferro-alloys have to be added at the final stage, and when the right carbon contents have to be carefully maintained, the induction furnaces present great advantages in enabling the whole process from start to cast to be under most accurate control. The manufacture of these special steels is becoming every year more important. Moreover, there are certain qualities which can be best obtained by electric-made steels, such as power of resistance to shock. Engineers are in the habit of testing steels by ascertaining the stress in tons per square inch which must be applied before the steel bar undergoes a permanent strain. This is called the elastic circuit. Also the contraction in area at this point, and the breaking strain and contraction in area at rupture are measured. These figures, however, give us only what may be called the static qualities. Steel as used for rails, wheels, axles, and machinery generally, suffers severe vibration, and it is, therefore, now customary to apply a test of its dynamic qualities or resistance to shock by ascertaining what number of times a bar of steel can be rocked backwards and forwards by rapid shocks or blows before rupture.

Certain elements introduced into carbon-steel have an enormous effect in increasing its static and dynamic qualities. Thus, for example, vanadium in quite small percentages acts like magic. The following are some figures taken from a research by Professor Arnold, of Sheffield. Thus a bar of Swedish iron had an elastic limit of 26,800 lbs., and contraction in area of 50 per cent. When alloyed with 0·85 per cent. of vanadium its elastic limit rose to 45,120 lbs., and contraction in area to 72 per cent. Here we have a striking improvement in elasticity, resilience, and ductility produced by less than 1 per cent. of a foreign element. Again, the effect on carbon steel is equally marked. Taking steel with 1·1 per cent. carbon in it and adding increasing percentages of vanadium the elastic limit and contraction in area varied, as shown in Table I.

Hence, the best result seems to be obtained by 0·58 per cent. of vanadium. In an excellent article on vanadium steel in *Cassier's Magazine* for June, 1910, Mr. W. E. Gibbs gave some astonishing figures as showing the superiority of vanadium steel to ordinary steel. Two pieces of steel, one ordinary carbon steel the other

TABLE I.

Per cent. of vanadium.	Elastic limit in lbs. per sq. inch.	Contraction in area in per cent.
0·00	67,000	7
0·14	96,120	6·9
0·29	99,320	10
0·58	144,800	7·6
0·77	131,300	9·3
1·11	120,600	17·6

vanadium steel, 4 in. long and ⅜ in. square, were fixed at one end and the free end vibrated by shock ¼ in. each way. The tempered carbon steel broke after forty movements, the annealed carbon steel after 250, the annealed vanadium steel after 500 vibrations.

The best steel for moving machinery is a chrome-vanadium steel, and at present has no superior for motor-car axles and crankshafts, as shown by the following figures:—

TABLE II.

Steel sample.	Elastic limit in lbs. per square inch.	Contraction of area in per cent.	No. of alternating shocks to fracture.
Carbon Axle .	41,330	61	960
Nickel Axle .	49,270	58	800
Vanadium Axle . .	63,570	61	2,700
Vanadium Crankshaft	110,100	58	1,850
Vanadium Gear . .	224,000	39	800

The vanadium can be introduced into the steel before casting in the form of a ferro-alloy. Although vanadium itself is a very infusible metal, yet its alloy with iron in the proportion of 1 : 2 melts at 1,400° C.

It may be an advantage to give by way of conclusion some figures as to the cost of producing steel from scrap-iron by certain of the types of electric furnace described in the previous lecture. Taking, for instance, the Girod 2-ton arc-resistance furnace, charged cold with scrap-iron and turnings, the cost of melting a ton of steel has been found to be as follows:—

	£	s.	d.
2 cwt. of lime, 2 cwt. of iron ore . . .	0	2	6
Added alloys	0	4	0
Electrodes	0	4	9
Labour . . . . } Upkeep of furnace, wear and tear. . . }	0	12	0
Power 1,000 kilowatt-hours, say at ¼d. per kilowatt-hour	1	0	10
	£2	4	1

Exclusive of cost of scrap.

If the furnace is charged with liquid steel from a converter or Siemens furnace, and the electrical process is a mere refinement, then the cost would be reduced to :—

	s.	d.
¾ cwt. lime and additions	1	7
Electrodes	1	7
Labour	2	5
Furnace upkeep	4	0
Power 300 kilowatt-hours, say at ¼d. per kilowatt-hour	6	3
	15	10

The prime cost of such a furnace is about £340, together with £120 for fittings, regulator and leads. A 400 h.-p. dynamo is required, the cost of which will be about £590, exclusive of engine or driving power. Hence we may say that the electrical plant for a 2-ton furnace will cost rather above £1,000.

Some details as to cost of working a Röchling-Rodenhauser induction furnace have been given in a paper by Mr. J. Harden (see *The Electrician*, March 18th, 1910). The furnace was charged with a basic Bessemer steel taken hot from the converter, having the composition, C = 0·3, S = 0·07 to 0·08, P = 0·06 to 0·07 per cent., and was refined in the induction furnace so as to finish with a composition C = 0·14, Si = 0·01, Mn = 0·41, S = 0·032, P = trace per cent. The weight of the finished ingot was 7,000 kilograms, and the materials and alloys used were as follows :—

	s.	d.
Lime, 550 kilogrammes, at 10s. per ton	5	6
Roll Mill Scale, 30 kilogrammes at 13s. per ton	0	4
Ferro-Silicon (50 per cent.), 30 kilogrammes at 200s. per ton	6	0
Ferro-Manganese (80 per cent.), 20 kilogrammes at 180s. per ton	3	6
	15	4
Per 1,000 kilogrammes	2	2½
Power consumed, 1,381 kilowatt-hours = 197 kilowatt-hours per ton at ¼d. per kilowatt	4	2
Lining of furnace	0	10
Labour	2	0
Cost per 1,000 kilogrammes = 1 metric ton	9	2½

Hence for something less than 10s. per ton, this basic steel was converted into a high-class steel suitable for tubes of marine boilers.

In large steel and iron works the electric power required can be obtained from blast furnace gases and gas-engines at a very low cost.

Those who desire to follow up this brief sketch of the technical applications of electric heating may be referred to the following books :—

THE POPULATION OF THE EMPIRE.

In a paper read recently before the Royal Statistical Society, Sir J. Athelstane Baines, C.S.I., gave some interesting results of an attempt to analyse the expansion of the Empire in area and population during the Victorian Era.

He took 1841 as the starting-point, not for historical reasons only, but also because shortly before that date there appeared the first methodical review of British possessions abroad, including a careful estimate of the population of each unit at the time. Of course, the information available regarding the population of many of the colonies is very defective up to 1871, and is even now a matter of estimate only, so that recourse must be had in such cases to computation upon the best data available.

"Accuracy being thus qualified," said Sir J. Athelstane Baines, "the population in question increased between 1841 and 1911 from 203,221,000 to 418,735,000, or by 106 per cent. The first point is to distinguish between the growth of population upon existing territories, and the increase due to the acquisition of new possessions. The population of the Empire of 1841, then, expanded, according to my estimate, by 68·2 per cent. The balance of the increase, amounting to 37·8 per cent., is to be credited to territory added since that date. Here again, however, the element of growth comes in as the acquisition took place at different intervals; and, so far as I can see, 10·5 per cent. out of the 37·8 per cent. increase occurred since the territories became part of the Empire. We can, therefore, set down the growth at 159,971,000, and the accretion by annexation at 55,543,000, or 78·7 per cent. of the one, and 27·3 of the other.

"The area has naturally not expanded in proportion to the population, and to the 8,526,641 square miles of 1841 the addition has been but 2,804,602, or 32·9 per cent. Starting with 24 persons per square mile, the ratio increased steadily to 36 in 1891, when a check to the growth of population in India, and the incorporation of large areas of sparsely-peopled territory in Africa reduced the proportion to 35, which recovered by

the end of the period to 37. Thus, whilst the population has doubled, the pressure upon the land has increased by but little over one half.

"Leaving on one side for the present the newly-acquired possessions, the rate of growth of the population of 1841 has been slow, considering the large area of thinly-peopled land available. In India, the seventy years added 58 to every 100 inhabitants of 1841, or 10 less than the general rate; and the United Kingdom, with a diminishing Irish community, acquired but 69, or 1 above the average. Far higher is the rate in the New World, especially in Australasia, which could scarcely be called peopled up to 1851. South Africa, too, seems to have multiplied its inhabitants tenfold; but, until the last ten years or so, Canada, with a relatively higher, yet still very sparse population, showed a remarkable lagging in covering its vast field of habitable territory, and was not, indeed, far in advance of the comparatively long-settled Ceylon. On the whole, if from the territories of 1841 we subtract India and this kingdom, the rate of growth will be raised from 68 per cent. to 467. By the year 1871 it had produced 281 for every 100 persons thirty years before, whilst the Empire of 1841 as a whole could only show 126; and this lead increased as years went on.

"We can thus appreciate the position occupied by India and the United Kingdom in relation to the enormous aggregate population of the Empire, as now constituted, an aggregate which has been estimated to amount to a quarter of the whole population of the earth. India alone contained about 85 per cent. of the British subjects of 1841, and even now, in spite of the more rapid growth of other countries, it accounts for no less than three-quarters. Taken together with this country it left, in 1841, only a little over 2 per cent. in the rest, a proportion which now stands at 14 per cent. The specific population, too, or the number of persons per square mile, is similarly affected by the exclusion of these two countries, as they are the only two, with the exception of the smaller territories of Ceylon and the West Indies, which support more than 100 to the mile. In the rest of the Empire, including the two last-mentioned units, the corresponding number was only 0·58 in 1841, 2·67 in 1891, and 6·20 according to the latest estimate. Putting the case in absolute, instead of proportional, numbers, the population of the Empire outside India and this kingdom in 1841 was about 4,500,000; in 1885 it was 15,000,000 and a little over; but by the end of the period with which I am dealing it had risen to 58,500,000."

A SILICA STANDARD OF LENGTH.*

The general properties of fused silica, and in particular its remarkably low coefficient of expansion, render this substance specially suitable for the construction of permanent length-standards of the highest class.

The coefficient of expansion of platinum-iridium, which has hitherto been the material almost exclusively employed in the best work, is about 9×10^{-6} per degree C., while that of silica over the ordinary range is about $0{\cdot}4 \times 10^{-6}$, *i.e.*, 1/20 of this amount. It is true that the best qualities of invar, M. Guillaume's nickel-steel, containing 36 per cent. Ni, have expansion coefficients comparable with that of silica, but experience has shown that while invar is eminently useful for working standards, it is quite unsuitable for primary standards, owing to its large thermal hysteresis. Fused silica, on the contrary, has been found to be practically free from this defect; it enjoys, in the matter of cost, an enormous advantage over platinum-iridium; furthermore, in view of the fact that primary standards are always handled by trained and skilled observers, its comparative fragility is of small consequence.

Modern methods of manufacturing and working silica have rendered it possible to construct a silica line-standard metre. The present model, the first of its kind, consists of a silica tube into which are fused at its ends optically-worked plane parallel slabs of silica. These carry the graduations, and their undersides are platinized. The graduations, defining the metre length, are made by cutting through the platinum film with a ruling diamond. The platinum deposit permits the ruling of very beautiful clean-edged lines.

The bar is supported at the Airy points so that the slabs are horizontal. The lines are viewed from above through the slabs, and are thus seen to advantage.

The apparent length of the standard is independent of any change of tilt of the cover-slips which are used to protect the platinum films. The thickness and position of the end slabs are so arranged that the image of each reference line lies in the "neutral plane" when the bar is immersed in water.

The silica metre was annealed at about 450° C., and shrank a little over half a micron in the process. It is anticipated that its future secular variation will be negligible so far as practice is concerned.

* By Dr. G. W. C. Kaye. Communicated to the Royal Society by Dr. R. T. Glazebrook, F.R.S.

THE BOARD OF EDUCATION EXAMINATIONS IN ART.

In a circular addressed to local education authorities and schools of art it is announced that the Board of Education intend in the near future to terminate the elementary examinations in art now conducted by them, and to substitute examinations of a more comprehensive character adapted to the needs of students who have reached a fairly advanced level in their studies, and who may reasonably desire to have their individual

progress tested in some such way as is open to students of other subjects by means of the various external examinations conducted by universities and other bodies. The examinations on the present lines will therefore not be indefinitely continued, and a new scheme of examinations, of which the details have not yet been announced, will be brought into force in 1913. It is proposed to invite some teachers in schools of art to assist in the conduct of these examinations.

Similarly, the existing series of tests for art class teachers' and art masters' certificates will be brought to an end in 1912, and new regulations will be issued for the award in 1913 and subsequently of qualifying certificates for teachers of art, upon conditions which will secure, in addition to high artistic attainments, the advantages of a general education and of a suitable course of professional training at some institution recognised by the Board for the purpose.

The merits and defects of the national competition have been the subject of much discussion in recent years, and the Board are satisfied that it may be capable of becoming more useful than at present for the purpose of affording an opportunity to the public of seeing the best work of which the most advanced students of schools of art are capable. They propose therefore to invite some experienced head-masters of schools of art and others to consult with them as to the lines upon which a reformed competition can best be established. If a satisfactory scheme can be framed, the Board will arrange a suitable place for the exhibition.

It is also hoped at an early date to effect some readjustment of the various scholarships and exhibitions for students of art which are now awarded or aided by the Board, so as to secure liberal opportunities of obtaining advanced instruction in art to intending teachers and other students throughout the country. In this connection, the Board give notice that the award of local free studentships will be made for the last time in 1911, for tenure during 1911-12, and that the award of local scholarships in art and the aid given to local exhibitions in art may not be continued, or may be continued under new conditions, after 1911, as may be necessary for the purposes of the readjustment contemplated.

Finally, the Board propose to constitute for a term of three years from September 1st, 1911, a standing committee of advice for education in art, upon which their officers will have the assistance of eminent artists, including those appointed as professional examiners for the new examinations and as visitors to the Royal College of Art, of teachers in schools of art, and of manufacturers and others engaged in the industries most dependent upon art. It will be the first duty of this committee to assist the Board in working out the detailed schemes which will be necessary in order to carry out the changes foreshadowed in the circular.

THE BRAZILIAN TOBACCO INDUSTRY.

Nearly two hundred years ago the Colonial Government at Bahia interested itself in the economic situation affecting the growth and marketing of tobacco, and from that time its production has been of great importance in Brazil, and has in some districts been almost the entire source of income to the inhabitants. As early as 1796 the exportation of tobacco from Bahia to Portugal had attained considerable proportions. The exports from that colony, later a province, increased regularly until the close of the monarchical period in Brazilian history. At the time of the establishment of the Republic the advantage of regularly-organised labour was lost to tobacco producers, and the annual production has, on the average, remained almost stationary since that time. At present, tobacco forms the sixth item in importance on the list of Brazilian exports. Of the total exports of tobacco from Brazil, about 95 per cent. is shipped from the port of Bahia, the next largest amount being from Porto Alegre. Over 92 per cent. of the exports are purchased by Germany, Argentina taking most of the balance. The State of Bahia has, since colonial times, been the centre of the tobacco industry of Brazil. Practically all the coast regions of this State produce tobacco to a greater or less extent. In fact, most of the coast regions from the State of Maranhao south have tobacco-producing districts of varying importance. The area of greatest production is a comparatively small section of the State of Bahia, centring about the bay and port of that name. Of late years a somewhat intensified cultivation has been developed in Rio Grande do Sul, and in southern Minas Geraes. There is also a district of somewhat heavy production in eastern and southern Pernambuco. The State of Bahia, according to the United States Consul-General at Rio de Janeiro, exports to other parts of Brazil an average of about 3,000 tons of tobacco per annum, in addition to an average of 22,500, or perhaps 25,000, tons sent abroad. Manufactures of tobacco in the shape of cigars, cigarettes, and pipe tobacco, shipped from Bahia to other Brazilian ports, amount to about £100,000 annually. Probably the second most important areas producing tobacco are in the State of Minas Geraes. Shipments of leaf, and what is called roll tobacco, prepared for pipe and cigarette smoking, from that State amount to about 3,500 tons annually. One of the distinctive forms in which tobacco from that State is prepared, is that of a long roll of very dark and compact leaf which is sold retail at so much a yard. The cigarette smokers in the interior whittle off the necessary amount from the end of such a roll for cigarettes. Rio Grande do Sul has some tobacco-producing areas, which are fast becoming second only to those of Bahia. There is also a notable increase in the attention given to the cultivation of tobacco in the State of Santa Catharina. In Sao Paulo the industry has become decadent with the growth of the coffee industry. While there are no

available figures covering the total production of tobacco in Brazil with any accuracy, it is estimated that this production is about 36,500 tons annually. Experts in Brazilian agriculture unite in affirming that methods of growing tobacco, gathering the crop and curing it, have changed little, if at all, since the days of the early colonists two centuries ago. Practically nowhere is there any idea of tilling the soil and cultivating the crop with an instrument more modern than the spade. As a consequence, very few planters cultivate more than what is known in the language of the country as a "terefa," an area about equal to four acres. It is stated that well-fertilised land in the better districts of Bahia will, under existing conditions of culture, produce a maximum of 800 pounds per acre, but the average production is not much, if any, above 300 pounds per acre. In many districts from Bahia northward, tobacco is planted in any soil which will not produce sugar-cane or cotton. In the best tobacco-producing areas in the Bahia district the soil is black, heavy, and usually very rich, formed of limestone. In the States of Alagoas and Sergipe, just north of Bahia, the best tobacco and also sugar-cane soils are of a similar character. In the latter States, and in the tobacco-producing areas northward, a light, sandy soil is also considerably devoted to tobacco, as is also the case in Minas Geraes. It is generally accepted that with the exception of two or three varieties of island tobacco grown in New Caledonia, practically all known varieties of tobacco are grown in Brazil. Among others, there are a large number of varieties indigenous to the country. In the south of Brazil a variety very common is the *Nicotiana alata* and the *N. Suaveolens*. A variety very common in the hotter regions is called the *Nicotiana chinensis*, cultivated also in Cuba and Porto Rico. Practically all the varieties grown in Maryland, Virginia, and Cuba are common in Brazil. The tobacco produced is used for all purposes, that of Bahia only being suitable for really good cigars. Many of the cigars manufactured in Bahia compare, it is said, favourably with medium-grade Havana cigars. The greater part of the tobacco is strong, though some very good mild tobacco is grown in Bahia, and of late in Rio Grande do Sul. In Bahia planting begins in March and extends throughout May, the plants being started in hotbeds and set out in from one to two months. In the south, planting does not begin until the opening of the hot season in November. When the plant begins to leaf the lower buds are cut in such a way as to cause the stock to branch. The tobacco cut from the main stock is considered of first quality, and that cut from the branches of second and inferior grade. The plant is not allowed to bloom, but is topped in most regions, the leaves being cut as they ripen. In the curing of the crop the general rule is to air-dry the leaves in sheds, but in practice the leaves are frequently allowed to lie for a long time on the ground, and even exposed to wet weather for some time before being cared for. There is no doubt that Brazil offers a great opportunity for tobacco production, and when scientific and modern agricultural methods have been more generally adopted, the country will be a much greater factor in the world's tobacco trade than it is at present.

HOME INDUSTRIES.

The Transport Trade Strike.—The seamen and firemen who commenced the transport trade strike have been much more successful than it was generally expected, not without reason, they would be. Increased wages were their principal desire, and these were conceded by leading steamship companies with hardly the semblance of resistance. The benefits secured are largely due to the demand being made upon a favourable market, and not as the result of a strong organisation—which was notoriously lacking—on the part of the workmen concerned. Whether, in the absence of such an organisation, the men will be able to retain what they have won remains to be seen. So far as the seamen and firemen are concerned, the strike would have ended almost as soon as it began but for the fact that much larger bodies of dockers and carters had made it impossible for the business of the shipowners to be carried on until an agreement had been arrived at with them also. The seamen and firemen have secured a present rise of 10*s*. in wages; besides concessions in the matters of medical examination, representation, and other subsidiary matters, together with recognition of their Union. Substantial benefits also accrue to the carters. The men have not got all they set out to get, but they have obtained considerable financial benefits, and the conditions of employment in many of the grades will be greatly improved. It may be hoped that things will now go on smoothly in the shipping industry, but the settlement does not, of course, touch the admitted shortage of British seamen, which is compelling shipowners to employ Asiatics, or to lay up some of their ships. Upon this point a suggestion has been made that seems to deserve consideration. It is that the Board of Trade might consider whether the time has not come when it might wisely relax some of the restrictions imposed on the shipment of seamen, and, so far as they are harmless, restore to some extent the facilities which formerly existed. For instance, years ago it was the custom of many owners to secure a supply of the very best type of seamen from the fishing districts. During the off seasons fishermen were only too willing to go a voyage or two in steamers so as to fill up their time, and shipowners used to secure these men through local agents. The Board of Trade, however, made it a penal offence for anyone to supply seamen unless they received a licence from the Board. The object of the legislation was ostensibly to put down crimping, and it was never intended to apply to cases such as are referred to above. The effect of the legislation was, however, to stop the supply of fishermen, as licences were refused,

and to increase shipowners' difficulties in securing the best type of men. It seems a little absurd that in engaging seamen an owner cannot be represented by a responsible agent.

The Bradford Woolcombers and the Auctions.—The strike among the woolcombers at Bradford is over, and work has been resumed on the old conditions. A prolongation of the strike must have seriously affected values at the London auctions. At the auctions held last week, prices did not fall quite so much as was generally expected. No class of wool was more than 5 per cent. down, except New Zealand slipes, which fell about 7½ per cent. Stocks and raw material at Bradford are heavy, and it is hardly to be expected that the opening rates will be maintained throughout the auctions. Instead of there being any shortage of supplies, they are much heavier than was expected, and some Bradford merchants and brokers have been asked to take off the market a sufficient quantity of New Zealand crossbreds to prevent any serious fall in values, but this would be a very doubtful experiment. Notwithstanding that during the present year consumption has been at a maximum, the carry-forward from one auction to another has gradually increased, until it has reached nearly 40,000 bales, and the bulk of the new clip is almost due. On the other hand, the demand for goods both at home and abroad, is slackening. The shipments from Australia for the wool year 1910-11, which ended on June 30th, are put at 1,975,000 bales, or an increase of 54,000 bales, compared with the previous season, whilst from New Zealand the shipments amounted to 493,000 bales, a decrease of 20,000 bales.

The Cotton Supply.—Messrs. Neill Brothers have issued a circular on the position of the cotton supply, in which they say that, in the matter of distribution, the noteworthy feature is the extreme smallness of the exports to Great Britain, which have only amounted to 22,000 bales for the whole period, against 119,000 last year. The visible supply for Great Britain, it is pointed out, is now only 72,000 bales above that of last year, though early in March the excess was 400,000 bales. "After this date last year America still exported 100,000 bales to Great Britain. This year practically nothing is coming, and it is only too probable that the supply of American cotton in this country will dwindle to a dangerously low point between now and about October 10th, which is the date when the smallest Liverpool stock usually occurs." Messrs. Neill's comparative estimate of the world's consumption of American cotton for the season is as follows:—

	1910-11.	1909-10.
Great Britain	3,050,000	2,750,000
Continent	4,300,000	4,375,000
U.S. North and Canada	2,400,000	2,450,000
,, South (takings)	2,350,000	2,342,000
Japan, Mexico, etc. (takings)	150,000	115,000
Total to be consumed at mills	12,250,000	12,032,000

Messrs. Neill think, however, that their estimates for Great Britain may be too small. As to the new crop, they speak of it as very hopeful, but it must be remembered that there are two months of the hot season still to reckon with, to say nothing of the subsequent dangers and vicissitudes.

The Silk Trade Dispute.—A section of the Macclesfield operatives are threatening to strike unless their demands are conceded, and should work be stopped, dyers, weavers, soft silk winders, warpers, and others, will soon be idle for want of material, and the whole of the industry in the town may be brought to a standstill. The demands of the men include (1) increased wages; and (2) the abolition of the bounty system—a small extra payment made to workers who get through a given quantity of work in the week—the contention being that this system does not give them more than an average addition to their money of 3*d.* a week. The women's wages at present range from 10*s.* a week for winders and cleaners, to 12*s.* for danters and 12*s.* 6*d.* for parters. They ask for an advance of 1*s.* a week all round. The men are paid as follows:—Single spinners (mostly youths) 14*s.* a week, double spinners 16*s.* 6*d.* a week, and throwsters £1 a week. In their case a rise of 2*s.* a week is demanded.

The Insurance Bill and Spinners.—Mr. J. M. Thomas, who is a member of the Parliamentary Committee of the Federation of Master Cotton Spinners' Associations, makes out a strong case for his contention that the contributions proposed to be levied both upon the spinner and the operative are out of all proportion to the sickness benefits which the operatives are likely to receive under the Bill. Mr. Thomas gives two typical instances:—Firm No. 1.—Employs 301 males and 142 females. The combined contributions from operatives and employer amount to £616 9*s.* 2*d.* per year of fifty weeks. Taking the experience of illness at this mill, which amounts to, at the outside, not more than three females and two males per week, or, put in another way, is equivalent to three females and two males being absent for a whole year of fifty-two weeks, the sickness benefit received by such five persons would be £110 10*s.*, or less than 18 per cent. of the combined contributions. Firm No. 2.—Employs 143 males and 64 females. Contributions paid would be £288 10*s.* The sickness experience at this mill is not more than one person per week, and the benefits received, assuming the sick person was always a male, would be £26 per year, or less than 9 per cent. of the combined contributions. The total sickness benefit likely to be received in accordance with the past experience at these two mills is about £136. A contribution of ½*d.* each per week from the employer and operative would realise £130.

The Insurance Bill and Women.—A large number of representative women have issued a letter in which they contend that the Insurance

Bill, if passed into law in anything like its original form, will inflict great injustice upon women. For instance:—A domestic servant enters service at fifteen and marries at thirty-five a small shopkeeper. After marriage she devotes herself to her household duties and perhaps to the management of the shop. She thereupon ceases to be "employed" within the meaning of the Act, and is not allowed to continue even as a voluntary contributor (C. 34) (4). If she predeceases her husband she never gets any advantage for the twenty years' contribution she made before marriage. If she survives her husband and supports herself by the shop or by some kind of jobbing labour she can only benefit under the Bill by becoming a voluntary contributor, in which case she will have very much reduced benefits compared to the employed contributors. Compare with this the treatment of the male worker under C. 71. He at sixty is entitled to receive repayment of the amount by which his contributions have exceeded the unemployed benefit received by him. Again, no person who is receiving board and lodging from an employer is to get any sickness or disablement benefit (C. 8) (7). This will hit the domestic servant class very hard. At the last census there were upwards of two million female servants in the United Kingdom. There is no security in the Bill that women shall be admitted to approved societies. There is nothing to prevent any of the existing societies adopting a sex disqualification, and under the bill this may be the prudent thing for them to do. It is noticeable that approved societies are precluded from adopting an age disqualification (C. 24). There are many other provisions of the Bill to which women not unnaturally object. The points indicated above suggest that their grievances in relation to it are substantial, and in some respects the Chancellor of the Exchequer has expressed his readiness to meet them.

NOTES ON BOOKS.

The Essentials of a Country House. By R. A. Briggs, F.R.I.B.A. London: B. T. Batsford. 7*s*. 6*d*. net.

Mr. Briggs has had very considerable experience in the building of country houses, and he has already published at least three volumes dealing with bungalows, cottages, and country residences. In the present book, under the heading "Essentials," he treats of a great variety of subjects, such as situation, aspect and soil, plan, porches and vestibules, halls and staircases, the various rooms, doors, windows, fittings, stables, garages, lodges, gardens, etc. The text is illustrated entirely from photographs and plans of houses erected from his designs and under his own supervision, at costs ranging from £1,250 to £4,600. Many of the illustrations are exceedingly pleasing, but they would have gained in variety had they not all been taken from the same source. Mr. Briggs, in spite of some annoying little mannerisms of style—as, for instance, his habit of addressing the reader as "dear madam"—has much sound and sensible advice to offer, and his book should, as he hopes, prove useful in helping those who intend to build to come to some definite conclusions before they consult an architect.

Whittaker's Arithmetic of Electrical Engineering. Second Edition. London: Whittaker & Co. 1*s*. net.

This little book contains 72 worked examples and 300 graduated exercises, a large number of which have been taken from the City and Guilds of London Institute examinations in electric lighting and power transmission, and telegraphy and telephony, and from the Board of Education examinations in electricity and magnetism. It forms one of Messrs. Whittaker & Co.'s well-known series of Handbooks for Electrical Engineers, and will be much appreciated by the technical students for whose use it is intended.

GENERAL NOTES.

The Iron and Steel Institute.—Arrangements have been made to hold the autumn meeting of the Iron and Steel Institute at Turin on Monday and Tuesday, October 2nd and 3rd, 1911. The provisional list of papers expected to be submitted for reading is as follows:—(1) "Report on the Mineral Resources of Italy," by various authors. (2) "On the Autogenous Welding of Metals," by Dr. Francesco Carnevali (Turin). (3) "On the Application of Electrical Energy to the Manufacture of Iron and Steel in Italy," by Cav. Ing. Remo Catani. (4) "On the Present State of the Iron and Steel Industries of Italy," by Signor Comm. Luigi Dompé and Cav. Francesco Saverio Pucci. (5) "On New Industrial Processes for the Cementation of Steel," by Cav. Professor Dr. Federico Giolitti. (6) "On Cementation with Gas under Pressure," by Professor Dr. F. Giolitti and Dr. Francesco Carnevali. (7) "On the Transformation of Steel within the Limits of Temperature employed for Heat Treatment," by Louis Grenet (Argenteuil, France). (8) "On Basic Slag," by V. Adolphe Kroll, jun. (Frankfurt-am-Main). (9) "On the Use of Titanium in Iron and Steel," by C. V. Slocum (Pittsburg). (10) "On the Physico-Chemical Properties of Slags," by Professor J. H. L. Vogt (Christiania).

Co-operative Dairies in Italy.—Co-operative dairies originated from the necessity of using milk for industrial purposes. They had their origin in the mountains and first developed there, where property is much divided and association becomes indispensable if a profit is to be made on the milk. In the fourteenth and fifteenth centuries, in several Alpine valleys, the milk was brought together and

subjected to the necessary treatment in common. This is the most ancient form of rural co-operation. The first phase was the system "turnario famigliare," or the reciprocal loan of milk. After that they passed to the system "turnario sociale," and only in more recent days is found the real joint enterprise, in which each member merely consigns his milk to the association which sells the common produce. In the first system the milk is treated successively in the houses of each associate. In Italy this system is still followed by the co-operative dairies of Osoppo, where the rearing of the cows and the whole treatment of the milk is done exclusively by women. In the system "turnario sociale" the milk is treated in a depôt possessed in common, the plant and utensils being also in common, under the management of a "casaro" (cheesemaker) appointed by the group of associates. Only a few years ago this type was common to nearly all the co-operative dairies of Upper Venetia.

The American Tinplate Industry.—It appears from an examination of the monthly trade returns of the United States that during the first ten months of the fiscal year 1911 (July 1910-April 1911) both the tin imports and the tinplate exports of the United States exceeded all previous records for a similar period. The total imports of pig-tin, of which England and the Straits Settlements are the chief sources of supply, amounted in the ten months ending with April 1911 to 92,374,000 pounds (compared with 86,464,000 pounds in the same months of the preceding fiscal period), valued at £6,963,000. The exports of tin and terne plates in the ten elapsed months of the current fiscal year aggregated 50,370,000 pounds (compared with 21,183,000 pounds in the corresponding period of 1910), valued at £373,000. The production of tin and terne plates in the United States in the calendar year 1909, the latest for which statistics are available, was 1,371,000,000 pounds, the largest total for any year in the history of American production, and as the importation of pig-tin for use in this line of manufacture was larger in the calendar year 1910 than in 1909, and is also larger in the accumulated months of the fiscal year 1911 than in the same months of the fiscal year 1910, it may be assumed that the production of tinplate in the United States is still increasing. Canada is the chief market for the tinplate exported to foreign countries, but large and growing shipments are now being made to Alaska and Hawaii, for use in their canning industries.

Automobile Engineering Apprenticeship Scheme.—A committee of the Incorporated Institution of Automobile Engineers has been collecting information from many large motor-car manufacturers and others as to the practice in vogue in their works with regard to the admission and instruction of pupils and apprentices. This information has now been tabulated, and will be placed at the disposal of parents seeking advice on the subject, for which purpose application should be made to the Secretary at 13, Queen Anne's Gate, Westminster, London, S.W., by letter in the first instance. It is hoped that by this means parents will be saved a great deal of trouble and anxiety, and possible expense, by being placed in a position to have access to information extending over a very much wider area than they could obtain by their own unaided efforts, and it is also hoped that through the Institution the various works will be brought into contact with those youths who are likely to show themselves specially apt in the branch of the industry in which they are to be placed.

International Shipping and Oil Engine Exhibition.—An International Shipping and Oil Engine Exhibition is to be held in Newcastle-on-Tyne in November next, when it is expected that a large collection of the most highly-developed types of oil engines will be brought together. Oil engines are being with increasing frequency installed on large vessels, and huge oil engines are at present being built for the navies of various Powers.

The Scarcity of Meerschaum.—The valuable material from which meerschaum pipes are made is continually getting scarcer, and the important industry which has flourished in Vienna, Budapest, Nuremberg, Paris, and in the Thuringian town of Ruhla seems endangered. The manufacture of meerschaum pipes is much more important than is generally supposed. The town of Ruhla alone has been exporting, in round figures, pipes to the value of about £350,000 annually. The finest grade of meerschaum is found near Eski-Shehr, in Anatolia, Asia Minor, in a hollow which, in early days, was a lake, in which the meerschaum was precipitated. Meerschaum is also found in other places, including Thebes, the Bosnian mountains in the neighbourhood of Grubschitz and Nuendorff in Moravia, and in some parts of Spain and Portugal.

Number of Students at Paris University.—The total number of students at the University of Paris last year was 17,708, divided as follows:—

Law	7,871
Medicine	3,756
Pharmacy	871
Literature	3,310
Science	1,900

In the Faculty of Medicine there were 3,330 male and 426 female students, and as regards their nationality 3,020 were French (2,896 males and 124 females); of the 736 students of other nationalities, 434 were males and 302 females.

Electric Power-station at Antivari.—A concession for establishing an electric power-station at the Adriatic port of Antivari has lately been granted by the Government of Montenegro. The dynamos to supply the electric energy to be used for industrial purposes will be driven by water-power.

Journal of the Royal Society of Arts.

No. 3,062. VOL. LIX.

FRIDAY, JULY 28, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

EXAMINATIONS.

The results of the Intermediate Examinations (Stage II.) will be published early next week. The results of the Elementary Examinations (Stage I.) will be published about the end of August. The results of the Advanced Examinations (Stage III.) were published on the 6th inst.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

THE APPLICATIONS OF ELECTRIC HEATING.

By Professor J. A. Fleming, M.A., D.Sc., F.R.S., M.Inst.E.E.,

Pender Professor of Electrical Engineering in the University of London.

Lecture IV.—Delivered March 27th, 1911.

The Domestic Applications of Electric Heating.

In this last lecture we shall consider some of the applications of electric heating in connection with every-day life. Great as may be the present consumption of electric energy for private electric lighting, many competent judges are of opinion that a very large additional field for its use exists in connection with the generation of heat for domestic purposes.

At the same time it is clear that this widely extended use of electric energy in home life has not yet arrived in any large degree, and it will be desirable therefore to examine the reasons for this and discuss the retarding causes now in operation. Apart from minor uses which are not at present important, and leaving out of account the use of electric energy for motive power, the demand for heat in our houses arises from the necessity for water heating, air heating, and food heating. We have to consider the nature of the appliances, their durability and prime cost, and the cost of working; also their economy and advantages as drawbacks relatively to other methods of heating.

It will be well to describe first those operations and appliances which can be easily and accurately brought into comparison when using different methods of heating. Whilst leaving certain general questions for discussion later, we may say at the present moment that one cause retarding the domestic use of electric energy for heating purposes is ignorance of the methods of usage and of the cost, and hence any information which tends to dissipate this ignorance will unquestionably assist the experimental or tentative adoption of these newer methods of heating. Another and most influential cause is that houses are not yet wired properly for the supply of electric-heating current in our rooms.

Let us consider, first, some of the facts in connection with water heating, because the supply of hot water, in small or large quantities, is a prime necessity in modern domestic life.

Consider the energy required to raise any mass of water from the ordinary air temperature, say, 60° F., just up to the boiling point, or 212° F. This involves raising it through 152° F., and since one pint of water weighs 1·25 lbs. and one gallon 10 lbs., it is clear that to raise one pint of water just up to the boiling point requires 190 B.Th.U., and one gallon requires 1,520 B.Th.U. to be imparted to the water. Since 1 B.Th.U. is equal to 0·294 watt-hours, it is seen at once that the energy required to raise one pint of water from 60° F. to 212° F. is 55 watt-hours, and to raise one gallon through the same temperature requires 440 watt-hours.

As all heat can be reckoned in energy units, and since electric energy is supplied to our houses at so much per kelvin, or Board of Trade unit, and since one kelvin equals 1,000 watt-hours, it is obviously an advantage to measure each operation of heating, whether of air, water,

or food, by the energy in kelvins required to produce the desired effect. Hence to heat the gallon of water from 60° F. to 212° F. requires 0·44 kelvin. Otherwise, 2·27 gallons of water could be raised from 50° F. to 212° F. by imparting to it energy equal to one kelvin.

Electric energy is supplied in our houses by the corporations or electric supply companies at so much per kelvin, generally 4*d.* to 6*d.* for lighting and 1*d.* to 1½*d.*, or, in some cases, less, for heating. Hence, if we reckon our energy consumption in kelvins, it gives us at once the cost in pence, assuming it sold at one penny per unit. The heating of the gallon of water up to boiling point requires 0·44 kelvin, as far as the heating of the water itself is concerned. Again, to provide ten gallons of hot water at 110° F., raised from 60° F., for a bath requires 5,000 B.Th.U. to be given to the water, equivalent to an expenditure of 1,470 watt-hours, or 1·47 kelvin.

The above figures for the energy absorption do not, however, give us the cost of the operation because, owing to thermal losses, more energy has to be employed than that represented by the temperature rise of the known weight of water. The user has to pay for these losses Hence we cannot give an answer to the question as to the cost of the electric heating, even when the price at which electric energy is supplied is known, until we have ascertained the efficiency of the various types of electric kettles, boilers and water-heaters employed. By their efficiency, we mean the ratio between the energy actually employed in heating the water to the total amount given to the heater, this ratio being expressed as a percentage. The simplest method of heating water electrically, and one which requires least alteration in ordinary water-supply arrangements is to use an *immersion heater.* This consists of some kind of high-resistance substance, often a wire coiled compactly and enclosed in a water-tight tube, the ends being brought out above the water surface. When a current is sent through the wire it is heated and imparts its heat to the water. As regards the durability of the resistance wire, there is some difficulty in getting any metal other than pure platinum, which is out of the question, to stand heating continually if air has access to it without oxidation and consequent deterioration. Even if heated in air free access of air should be prevented. We must have a wire of high specific resistance, high melting-point, and as non-oxidisable as possible. Nickel or certain alloys of nickel, such as the alloy called Nichrome, appear to answer these conditions best. A durable heater can, however, be made with silundum or with kryptol enclosed in water-tight cases. The heating resistance should be as far under the water as possible, in order to accelerate the heating by convection. The three sources of loss are—(1) radiation, air convection, or conduction from the cistern or vessel containing the water; and (2) loss of heat by conduction out of the electrodes; (3) heat carried away as latent heat of evaporation by escaping water, vapour or steam. The water vessel must, therefore, be closed, and either well lagged with non-conducting composition or else highly polished on the outside to reduce these losses. A difference of opinion exists as to which procedure is the best. If the polished exterior is to be kept effective as a non-radiator it must be kept bright, and this involves periodic labour. It would be impossible in the case of a hot-water cistern of any large size, although feasible in the case of electric ovens and small water-heaters. An experiment showing the value of external polish in preventing loss of heat in electrical heaters was mentioned in the *Electrical Times* of October 31st, 1910, which we take the liberty of quoting verbatim:—

Two water-heaters, each containing two gallons, were placed side by side and connected to an electric supply. One was of cylindrical shape, and was of highly polished tin plate, *i.e.*, tinned iron. The other was of sheet copper of triangular form, painted a dark glossy colour. Both had loose fitting lids, both took 800 watts, and both were switched on at once, the polished vessel boiling in about 80 minutes, the other heater taking somewhat longer. When both were boiling vigorously, the current was switched off, and the vessels were left all night without being touched. The time of switching off was exactly 12.0 midnight. At 8.15 next morning the temperature of the water in both was taken carefully, with the result that that in the cylindrical and polished vessel was 112° F., and that in the triangular copper heater was 80° F., a loss respectively of 100 and 132 degrees in 8¼ hours. If the triangular vessel had been painted dead black, instead of having a glossy surface, the loss would, no doubt, have been more marked, but the difference in the two figures is sufficient to show that a very high degree of efficiency can be secured with vessels costing but a few shillings, provided they are constructed on the right lines, and are carefully polished in the first instance, and kept bright afterwards. In the above experiment, the conditions were in reality more favourable to the triangular vessel than to the cylinder, for the former was hung on a brick wall, and had its heating elements self-contained, while the cylinder was placed on a hot plate and left

there all night. A substantial loss by conduction must have resulted through the large metal surface of the hot plate, with which the water urn was in close contact.

Now this may be all very good from a purely scientific point of view, but in domestic use the maintenance of high polish means labour, and in the present state of the domestic servant question it is, to say the least, highly improbable that this labour can be secured. Hence, since ordinary cisterns cannot be polished on the outside, they must be well lagged with non-conducting substances. The best way is to enclose the metal water-cistern in a larger wooden box, and pack the interspace, which should be 4 to 6 inches thick, with magnesia, asbestos, cork powder, or slag-wool, or any good thermal insulator. The cistern should, of course, be covered and lagged on the top, and the wires connected with the immersion heater brought out through the lid. As an instance of the great importance of lagging, an immersion heater of this kind is now exhibited to you in operation taking 800 watts or 8 amperes at 100 volts. Two galvanised iron cisterns, holding about 3 or 3½ gallons, were obtained. One of these was left bare, and the other fitted into a larger wooden box, the interspace being filled in with wood shavings ; 2·5 gallons, or 20 pints, of water were then placed in each cistern, and the 800-watt immersion heater used to heat the water from 60° F. to 212° F. Theoretically this requires 1·1 kelvin (= 2·5 × 0·44), but actually in the lagged cistern it did require 1·32 kelvin, or 8 amperes, at 100 volts for 1·65 hours. Hence, the efficiency in this case is 83 per cent.

In the unlagged cistern the water could not be heated to boiling by 800 watts in any time. The thermal losses were so large that this rate of supply of energy was not sufficient to balance them. Hence, lagging is of importance in reducing the rate of supply of energy as well as increasing the efficiency. If the energy is supplied for 1*d.* per unit the above water-heating in the lagged cistern would have given us 2½ gallons of boiling water for 1·3*d.* This, however, is by no means the best that can be done. A large part of this loss is due to the heat carried away as latent heat of vaporisation by the escaping water vapour, and if this is to be prevented the cistern must be provided with a close-fitting lid and a condensing tube, so that the vapour shall be condensed and the warm water returned to the cistern.

With proper arrangements of this kind it is possible to raise the efficiency nearly to 100 per cent., but never quite, because some energy is carried off by heat conduction in the leads. Nevertheless, it is a fair statement to make that by an expenditure of 0·5 kelvin one gallon of water can be raised from 60° F. to 212° F., or with energy at 1*d.* per unit the gallon of water can be raised from 60° F. to 212° F. by an expenditure of ½*d.* A similar immersion heater on a small scale can be employed to heat a glass of milk or water by immersing the heater in the liquid and connecting it to any electric lamp socket. Thus, the small heater shown, made by Messrs. Isenthal, takes 200 watts or 1 amp. at 200 volts, and will raise one pint of water from 60° F. to boiling with an expenditure of 90 watt-hours, or 200 watts for 0·45 hour. This gives an efficiency of only 61 per cent., but the heating was conducted in a bare glass jar. Using a glass vacuum vessel or thermos bottle, the energy taken fell to 78 watt-hours

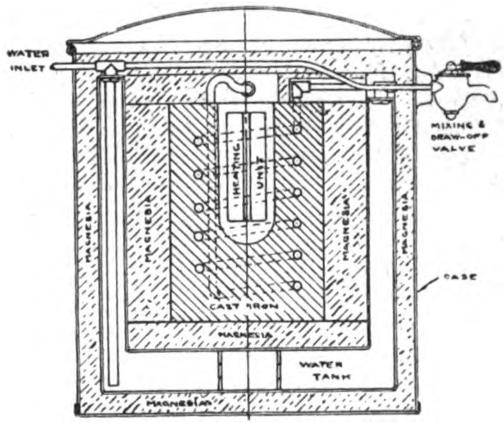

Fig. 34.—Section of Therol Electric Water-Heater (Spagnoletti).

and the efficiency rose to 71 per cent. Hence, at 1*d.* per kelvin, the cost is 0·078*d.*, or about $\frac{1}{12}$*d.* A very convenient way of warming milk, soup, or water at the bedside is to use a thermos bottle, and an immersion heater of the kind, and plug into a wall socket or lamp socket in the bedroom. On a much larger scale hot water is conveniently obtained electrically by an arrangement called a therol, brought out by Messrs. Spagnoletti, Ltd. It consists of a block of iron enclosing a coil of steel pipe (see Fig. 34). In the top of the block is a recess or cavity to contain the heating resistance, which is a Nichrome wire. These elements can easily be renewed, but are said to last two years or more. The block of iron is insulated by thick magnesia lagging. Outside this is a water-jacket, from

which the supply of water is drawn through the steel coil. This, again, is contained in a well-lagged vessel. The standard size of heater takes 200 watts—that is, 1 ampere at 200 volts, and is said to give 9 gallons of boiling water or 25 gallons of water at 110° F. per day.

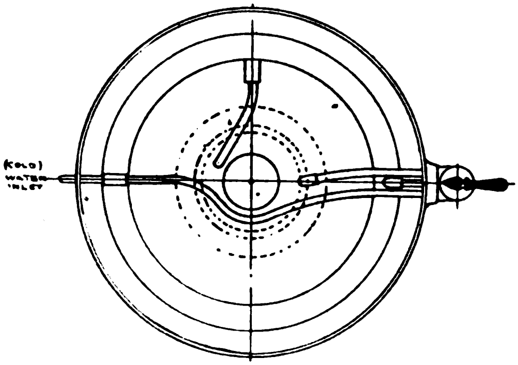

FIG. 35.—PLAN OF THEROL ELECTRIC WATER-HEATER.

In a factory experiment made with a therol having a 300-watt heater, taking 3·3 amps. at 95 volts run for 24 hours, and taking up therefore 7·5 kelvins, 38·4 gallons of water were drawn off at one run at 110° F. This implies that 384 lbs. of water had been raised 60° F. or 23,040 B.Th.U. imparted. The energy put in electrically was 7·5 × 3,400 B.Th.U. = 25,500. Accordingly, the efficiency of the heater in this experiment was 92 per cent. nearly. Now many corporations will supply electric energy at ½*d.* per unit for uninterrupted supply, and at this rate the cost of heating the 38·4 gallons of water to 110° F. would be 3¾*d.*, or about 1*d.* per 10 gallons.

The one defect of such an apparatus is the slow rate of heating, but Messrs. Spagnoletti have recently introduced an improvement called an accelerator in which a thermostat closes a circuit when the temperature of the water falls below a certain limit, and causes a relay to cut into circuit an additional 1,000-watt heater contained in the pocket of the therol, and so raises the temperature of the water in the reservoir more quickly again to the high temperature (see Fig. 36). A 200-watt therol fitted with 1,000-watt accelerator can give 130 gallons of water at 110° F. per day if required.

The importance of the use of the therol, from the supply station point of view, is that it provides a steady load, and hence enables a lower charge for the electric energy to be made, not only for the therol itself, but for other heating and cooking purposes. In poor neighbourhoods the supply of hot water publicly by charge at so much per gallon by some form of penny-in-the-slot system might be made a means of raising the load factor of public supply stations, and so reducing the cost of generation. Another similar water-heating arrangement has been brought out by the Armourduct Manufacturing Company under the name of a therma. In this appliance water is stored in a well-lagged cylindrical tank, and is heated by a wire-resistance made of a narrow ribbon of nickel alloy, wound specially on flat sheets of mica. There are two resistances—one low and one high—to effect the first heating, and afterwards by an automatic switch to maintain the water at 160° F. For the 15-gallon size the heating units take 2,000 and 150 watts respectively, the entire contents of the tank being raised from 60° F. to 160° F. in 2½ hours. According to these figures the efficiency should be 90 per cent., and the cost at 1*d.* per kelvin would be ⅓*d.* per gallon of water delivered at 160° F.

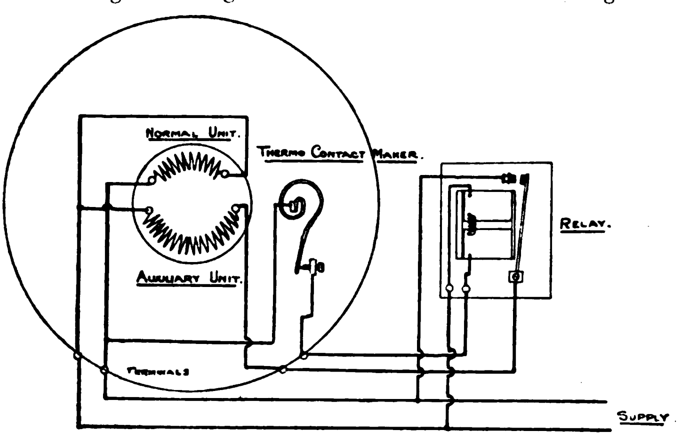

FIG. 36.—ARRANGEMENT OF CIRCUITS IN SPAGNOLETTI ACCELERATOR.

There is another water-heater called a Fuller geyser, in which the heating resistance is the water itself. The water passes through a chamber containing a porcelain cylinder with porcelain caps on each end. Inside this cylinder are a number of sheet platinum diaphragms separated by porcelain rings. Alternate diaphragms are connected together and to the electric supply mains. The cold water flows between the diaphragms and through circular apertures cut in them and is traversed by a current. The water is partly electrolysed and the gases escape with the steam. There is, therefore, no resistance to burn out. A geyser to deliver one pint of hot water per minute is said to take 1,000 watts. Hence sixty pints could be heated in one hour by an expenditure of one kelvin. This type of heater is apparently best adapted to deliver a small quantity of water rapidly, as for a wash-hand basin.

This leads us, then, to notice the various types of electric kettle and water-boiler for cooking and other small purposes. We may divide existing types of apparatus into two classes. There is first the type of kettle or boiler which contains in itself a heating resistance of some kind, and therefore is a special article. Thus, for instance, a Prometheus kettle has a double bottom, and in the cavity embracing the inner vessel is a band of high-resistance material between two strips of mica. Often two bands are used to give two rates of heating. The connection to the circuit is made by a flexible conductor and plug connection. In using such a kettle the current must not be switched on before the water is placed in it, and must be switched off before pouring the water out.

The efficiency of such a kettle can be measured by noting the power in watts and time required to bring a pint or quart of water from 60° F. just up to the boil. Thus with a Prometheus kettle of quart size, having two pints of water in it, it was found that 130 watt-hours were required to bring the quart just to the boil. It required 4 amperes at 100 volts for twenty minutes. The theoretical amount of energy required is 110 watt-hours. Hence the efficiency is 84 per cent.

A Prometheus saucepan taking 600 watts required 105 watt-hours to raise 1¾ pints to the boil, which is at the rate of 60 watt-hours per pint, or an efficiency of 91 per cent. Hence it is clear that water-heaters constructed on this plan can have an efficiency as high as that of a good dynamo or motor.

Another mode of electric heating for water-boiling or cookery is to employ an ordinary kettle or saucepan over an electric hot plate or incandescent radiator. Thus we may heat a silundum grid red-hot by a current and then put an ordinary kettle full of water over it as if it were a fire. In this case, however, the radiation losses from the heater are considerable, and the efficiency of heating becomes much less. An experiment made with a silundum heater and various kettles gave results as follows:—Using a bright tin kettle and one silundum heater taking 500 watts, it was found that one pint of water was raised from 60° F. to 212° F., with an expenditure of 117 watt-hours. This gives an efficiency of only 47 per cent. Using two silundum heaters in series taking 1,000 watts, the pint was boiled with 120 watt-hours and an efficiency of 46 per cent.

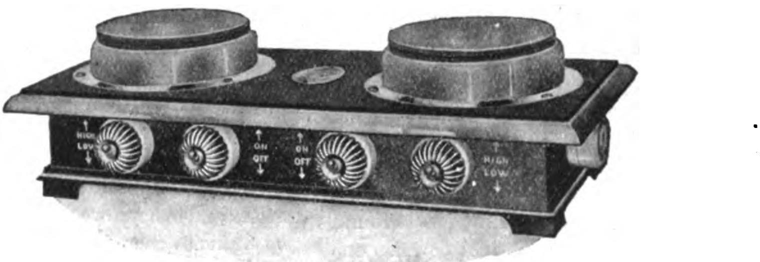

Fig. 37.—"Tricity" Hot Plate for Electric Cooking and Heating.

If a hot-plate heater is used, such as a Berry "Tricity" cooker (see Fig. 37), it is important that the kettle should have a perfectly flat bottom and make good contact with the heater; otherwise there is a loss in efficiency. Hence the class of kettles which are most efficient with gas-rings are not most efficient with electric hot plates.

In the case of ordinary coal-gas employed as a heating agent with the usual gas-rings we may reckon that each cubic foot of London gas at 60° F. and 30 in. barometer, has in it potential

energy available for heating equal to about 550 B.Th.U. This calorific capacity varies somewhat from day to day according to the chemical constituents of the gas. Since 1 B.Th.U. = 0·294 watt-hour, we may say that the intrinsic or gross calorific capacity of London gas is about 162 watt-hours per cubic foot, or 162 kelvins per 1,000 cubic feet. The question then arises: How much of this 162 kelvins can we utilise in water-heating?

I find much depends on the kettle and the gas-ring. For each kettle there is an appropriate size of gas-ring and certain rate of supply of gas, which gives the best efficiency (see Fig. 38).

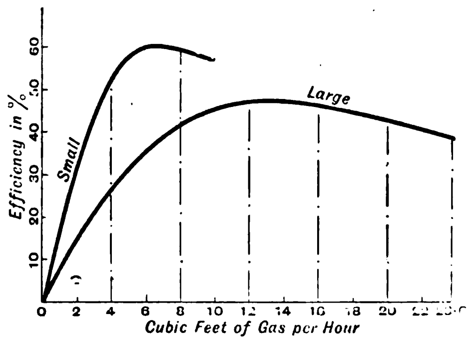

FIG. 38.—EFFICIENCY CURVES FOR LARGE AND SMALL RING BURNERS AT DIFFERENT GAS FLOWS.

Taking an enamel iron kettle holding one quart and putting it over a large gas-ring, it was found that it required 0·9 of a cubic foot to raise one pint of water to the boil. This means that energy equal to 146 watt-hours was supplied as gas burnt to impart 55 watt-hours to the water. The efficiency, therefore, is only 34 per cent. Using a smaller gas-ring, the gas burnt was only 0·67 cubic foot for the same duty, equivalent to an efficiency of 53 per cent. If a bright tin kettle was employed, the consumption was 0·61 cubic foot, an efficiency of 58 per cent., and if a "kwik" kettle, or one having water tubes in the base was used, the gas consumption fell to 0·55 cubic foot and the efficiency rose to 61 per cent.

Using three pints of water in a bright tin saucepan over a small gas-ring gave a consumption of 0·62 cubic foot per pint and an efficiency of 58 per cent.

It is clear, therefore, that using an ordinary tin or iron kettle over a suitable gas-ring we cannot obtain a much higher efficiency than 60 per cent. On the other hand, with the electric kettles we can obtain an efficiency of 80 per cent. or more. The ultimate question, however, is one of cost. If electric energy is supplied at 1*d.* per unit, then the best electric kettle will take 60 watt-hours to boil the pint of water, costing ·06*d.* The best ordinary kettle and gas-ring will take 0·55 cubic foot of gas, which, at 2*s.* 9*d.* per 1,000, will cost ·018*d.* Accordingly, for the small operation of boiling a pint of water, the gas has the advantage in mere cost, but many disadvantages from other points of view. If, however, we take into account the fact that gas burners in the hands of domestics are nearly always lit before they are wanted, and left burning after they have been used, the practical ratio between the cost of small water boiling by gas at 2*s.* 9*d.* per 1,000 and electric energy at 1*d.* per unit is not nearly so large as 1 to 3. It is more like 1 to 2, or even 1 to 1. As regards larger quantities it is easy to show that to provide ten gallons of hot water at 110° F. for a bath, raising it from 60° F., requires the expenditure of 2 kelvins. This at 1*d.* per electrical unit costs 2*d.* My experience is that to do it by gas requires 30 to 40 cubic feet of London gas, costing 1*d.* to 1⅓*d.* It must be remembered, however, that each cubic foot of gas requires, roughly speaking, two cubic feet of air to burn it, and that the products of combustion and imperfectly burnt gas have to be got rid of. This renders the use of gas geysers, gas kitcheners and gas heaters generally, except on a very small scale, impossible without adequate ventilation, and therefore the comparison of the two agencies merely on the basis of cost of gas and cost of electric energy is unfair.

As a final result we may say that water heating by electric current is not only practical on a large or small scale, but that even at the present cost of electric energy it is not at much disadvantage compared with gas at 2*s.* 6*d.* per 1,000, whilst if electric energy can be generally supplied at a cost of ½*d.* per unit for domestic heating, as it is in some places, the advantages will be all on the side of the electric heating. Furthermore, we may say that in the public supply of hot water for domestic purposes there is a source of revenue for electric supply stations which has hardly yet been touched.

We have in the next place to consider electric heating for other culinary purposes. A large part of the operation of cooking consists in exposing the edible material to such a temperature that if of animal nature the albumen in the flesh is coagulated, but not at such a temperature as to render it insoluble in the gastric juices. Also other operations involve the partial conversion of starches into dextrine, as well as the softening of animal or vegetable tissues by heat.

The heat for the purpose must be capable of ready variation over a range of temperature from 100° F. to 500° F.

The following are the temperatures required for various operations, on the authority of Senn, and are quoted from an excellent handbook called "Electricity for Everybody," by Mr. R. Borlase Matthews (published by the Electrical Press, Ltd., 37–38, Strand, London).

SAUCEPAN.

Fast boiling	212° F.
Simmering	180°–190° F.

OVEN.

Roast Beef	300° F.
Roast Mutton	310° F.
Game and Poultry	310° F.
Meat Pies	290° F.
Pastry and Cakes	320° F.
Bread and Puff Pastry	340° F.

FRYING.

Fish	360°–375° F.
Meat	370°–380° F.
Fritters	340°–375° F.
Whitebait	400° F.

In many operations, however, such as baking meat, the temperature has to be high at first and somewhat reduced later, but every oven should be capable of attaining and keeping a temperature of 400° F. The ordinary family cook is in the habit of using her hand as a thermometer, but a thermo-electric junction can be fixed in an oven and connected to a direct-reading voltmeter outside, and will give at once, without opening the oven door, the right temperature.

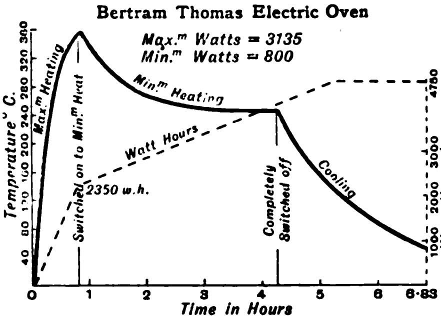

FIG. 40.—HEATING AND COOLING CURVES OF BERTRAM THOMAS ELECTRIC OVEN.

The electric ovens in use may be of two types: One which consists of an iron chamber heavily insulated with non-conducting material, in the walls of which coils of wire are embedded, which are heated by the current sent through them. As an excellent example of this type, we may mention the Bertram Thomas electric oven here exhibited (see Fig. 39), of which the heating and cooling curves are shown in Fig. 40. Two or three switches are generally provided, by means of which the heat is regulated. Such an electric oven has to be substantially built and well insulated to achieve its purpose. The second class of oven is nothing more than a light sheet metal box, highly

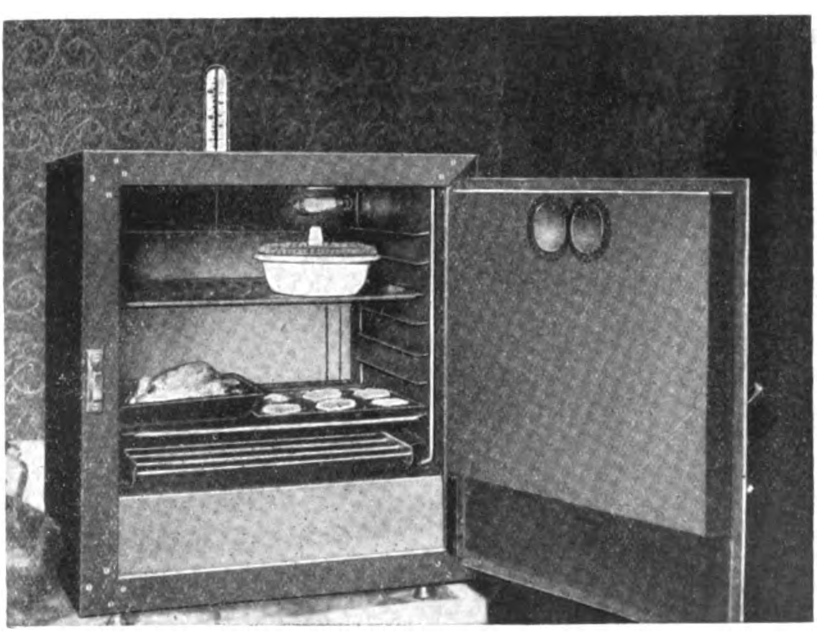

FIG. 39.—BERTRAM THOMAS ELECTRIC OVEN.

polished on the outside to prevent loss by radiation, placed over a hot plate in which heat is generated by passing a current through resistances. In the Berry "Tricity" system the heater

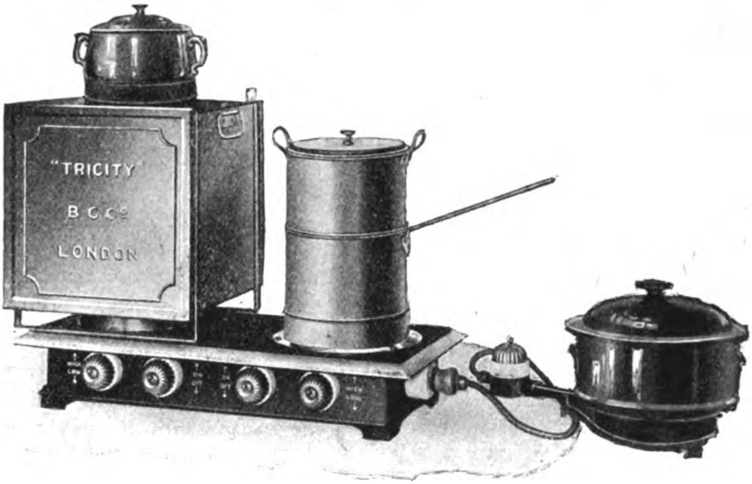

FIG. 41.—"TRICITY" COOKER. HOT-PLATES, OVEN AND STEW-PANS.

is a round iron plate containing the heating coil, which takes 800 watts, and is raised very quickly to 500° or 600° F., or something short of a visible heat. Over this plate can be placed a polished sheet-iron oven, and in the interior of this the culinary operations are conducted (see Fig. 41). In this case the radiation losses are kept small by the polish of the oven. In the Bastian system the heaters are Nichrome wires run at a low, red heat, and enclosed in quartz tubes (see Fig. 42). The oven is air-lagged and polished on the outside.

For frying or grilling we have the option of using the type of electric saucepans or grillers in which heating wires of a special alloy are embedded in enamel, the enamel being so composed that it has the same co-efficient of expansion as the wire, and does not, therefore, tend to break away from the wire when hot.

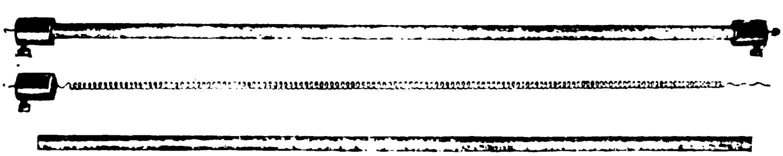

FIG. 42.—QUARTZ TUBES, WITH NICHROME SPIRAL WIRES, USED IN THE BASTIAN SYSTEM OF ELECTRIC HEATING.

Or we may use ordinary saucepans or grillers on an electric radiator in which some resistance material is heated to incandescence, this radiator taking the place of the coal-fire. Broadly speaking, we may say that when we use the special electrical vessel with embedded resistances we can obtain the highest energy efficiency, because we can most perfectly insulate it, and prevent the heat from escaping in directions where it does no work. On the other hand, such vessels are bound to be more expensive, heavier, and more fragile, or easily injured, than the ordinary culinary vessels. Hence they have less durability in ordinary domestic use.

On the other hand, those systems in which an electric heater or radiator is employed to take the place of the ordinary fire or gas-ring, and on which ordinary saucepans, kettles, or a similar class of vessel are used, may give less efficiency, in an energy sense, because there may be a greater wasteful loss of heat.

Now, the cost of cooking, apart from the cost of materials and wages, is made up of the cost of energy or fuel and the cost of the apparatus distributed over its useful life. Thus, if an electric kettle costs 15*s.* to begin with, and has to be repaired even only once a year at a cost of 5*s.* each time, and lasts, say, three years, we should have to consider the cost of the appliance as 10*s.* per annum. On the other hand, if an ordinary gas-ring and enamel iron kettle cost 6*s.* to begin with, and needs no repairs, but lasts six year, the cost of apparatus is 1*s.* per annum.

Hence the initial outlay and the cost of repairs and life of the appliance are a very important element, and have to be taken into consideration as well as the cost of electric energy as compared with gas or coal. Whatever type of oven may be employed, it is necessary to be able to regulate the temperature easily and quickly. Everyone knows that in cooking a joint of meat the temperature has to be high at first to coagulate the albumen on the outside and seal in the meat juices. Then the temperature has to be lowered to continue the process of cooking so as not to coagulate the albumen in the interior beyond a certain point. Hence switches have to be provided, giving at least three stages of temperature. Also a thermometer or pyrometer indicating the temperature in the interior, and it is a convenience to have a mica window and electric lamp—as in the Bertram Thomas oven shown in Fig. 39—so as to watch the process without opening the door. In using an electric oven, it is generally necessary to get up the temperature first before inserting the food, and this is most conveniently done when a thermometer is provided. The electric oven has, of course, the great advantage over the gas oven that the interior is free from the products of combustion.

There is, however, a large field for improvement still open in those appliances. As regards electric cooking apparatus generally the following qualities are essential. Anything required in ordinary domestic use has to be strong and simple and easily managed, and in the present state of the domestic labour market the less cleaning required the better. Hence such modes of connection to the circuit as porcelain two-pin wall-plugs and flexible cords are out of place. Highly-polished copper kettles and nickel-plated vessels look very pretty when new, but involve a great labour to keep bright, and lose much of their advantages as non-radiators if not kept bright. Most people cannot afford to keep a large number of spare duplicates. Hence expensive vessels must be so made that they cannot get out of order, which is very far from being the case with many of the present types of electric cooking apparatus. Some automatic arrangement must be provided which ensures that the resistance wire shall not be burnt out if the vessel is left empty. Such arrangement is provided in the case of electric cooking vessels and water-heaters provided by Messrs. Isenthal. Again, the advantages of low voltage are supreme in the case of electric cooking. It is nothing short of a crime to place in the hands of ordinary domestic servants electric cooking apparatus worked at 220 volts off one side of a 440 volt service. In the case of cooking by electricity, just as in the case of lighting by metallic filament lamps, the advantages are all on the side of alternating current supply, as then the voltage can be reduced to 50 or 25 volts, and be made safe in the hands of a child.

The chief fault of much of the present electric cooking apparatus is that it does not supply a sufficiently high temperature or supply heat quickly enough. In cooking it is necessary to be able to command high temperatures quickly for a short time. This is why such a simple operation as making a piece of toast is better carried out by the ordinary coal fire than by most of the electric toasters.

It is necessary to be able to force or delay the process of heating at pleasure, and the present electric cooking apparatus is deficient in this respect. Furthermore, many of the appliances in the market for electric cooking are either too costly or too flimsy. Cost, however, is a matter of production.

We are at present in the condition as regards electric heating in which we were in 1883 or 1884 with regard to electric lighting. The price of the electric energy cannot be reduced until the demand is greater and the cost factor improved. The demand cannot arrive until the facilities for using the current are given, and it will, therefore, only at first appeal to those who can make the necessary expenditure in wiring. What is now chiefly required as a preliminary condition is that the ordinary speculative builder, when erecting houses, shall provide separate and proper electric wires for heating circuits. Experience, however, shows that electric cooking is on a different basis as regards cost to electric water heating. When once an oven has been brought up to the cooking temperature the only reason for supplying more energy is to make up the losses by radiation and convection. It is possible to reduce these losses to a very small amount, and yet to maintain the required cooking temperature. In electric cooking the food is not contaminated with the products of combustion. Ovens can have a more uniform temperature in them than when heated by gas or coal, and also food, such as meat, wastes less or loses less in cooking by electricity than by gas, and has also a better flavour. As regards the costs of it, a rough-and-ready rule appears to be that when the cooking of a household is conducted entirely by electricity, it requires one unit (one kelvin) per day per person plus one

or two units for the energy losses. Thus six kelvins per day should do the cooking for four persons taking the usual three meals per diem, provided they are not elaborate.

We have, then, in the third place to consider the question of air-heating or house-warming by electric heating. In addition to food required for the sake of maintaining animal heat we find ourselves under the necessity of maintaining a certain internal air temperature if we are to be thoroughly comfortable, and the limits of this are rather narrow. We may say that 60° F. to 65° F. is the normal healthy room air temperature. If it falls below 45° F. or 50° F. we feel it cold, and if it rises to 70° F. or 75° F. we feel it to be warm.

Hence for comfort and health the air in which we live should be maintained as far as possible

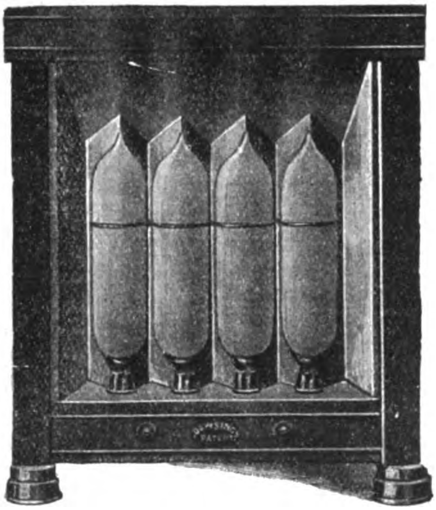

FIG. 43.—COMBINED LUMINOUS RADIATOR AND CONVECTOR, BY THE DOWSING RADIANT HEAT COMPANY.

at 60° F. But more: we are acutely sensitive to the hygrometric condition of the air, or to the percentage of water vapour in it. If it is very dry we experience sensations of enervation, and also if very moist. About ten litres of water vapour per cubic metre of air, or about 1 per cent. of water vapour by volume in the air, appears to be a comfortable amount. Also health and comfort are greatly determined by the organic matter in the air. Now the ordinary methods of house heating are acknowledged to be extremely unscientific and wasteful, yet nevertheless there is something to be said in favour of them, as they at least produce some degree of ventilation necessary to renew the air in our rooms and carry away the products of organic contamination. And it is not only necessary that the temperature and moisture should be kept within limits, but equally so that the organic contents of the air and its carbonic acid contamination should be kept below a certain amount. We all know that a room without a fireplace and chimney is never so healthy as one in which there is a fire. We shall not be able to afford time to discuss the advantages or disadvantages of heating by coal fires, anthracite stoves, gas fires, or hot air heating, but must confine ourselves to the problem of electric room heating. There are two systems of doing this, one by luminous radiators, first introduced by Mr. H. J. Dowsing, and the other by non-luminous heaters or convectors. Lately, however, the two systems have been combined by inventions due to Messrs. Dowsing and Huntley (see Fig. 43). Air, being very diathermous, can only be heated by being brought in contact with a hot body. If the radiating body is luminous, that radiant heat can only heat the air by falling on surrounding bodies such as the furniture and walls of the room, which absorb this heat, become hot, and in turn heat the air by contact. On the other hand, that radiant heat may heat our persons by falling on our clothes or flesh and heating them. What is really required, however, is the heating of the air generally. Nevertheless, most persons would agree that a source of luminous heat in a room gives it a cheerful appearance, and that a room heated by a hot-water or steam-pipe radiator is never so attractive as a room which has in it a gas or coal fire or luminous radiator of some kind.

It is important, as a preliminary to further discussion, to consider the amount of heat required to raise a given volume of air to a given temperature. At ordinary temperature and pressure 12·35 cubic feet of air weigh 1 lb. Hence 1,000 cubic feet of air weigh very nearly 80 lbs. The specific heat of air is 0·2375. Hence to raise the temperature of 1,000 cubic feet of air 1° F. requires 80 × ·2375 B.Thu.U., or 19·24 B.Th.U. = 5·65 watt-hours. Suppose the air is raised from 32° F. to 65° F. or through 33° F., then to raise 1,000 cubic feet of air from 32° F. to 65° F. requires 186·45 watt-hours, or 0·186 kelvin, or roughly one-fifth of a Board of Trade unit of electric energy. Suppose the room to be heated to be a room of about 2,500 cubic feet. Then to heat the air in this room from the freezing-point to a comfortable temperature of 65° F. would theoretically require only 0·5 kelvin. The air has, however,

to be renewed at least twice an hour for the removal of carbonic acid and organic products, and hence it would require at least 1 kelvin even for the mere air heating. Practically it would require far more than this, and a good deal more even, if the doors and windows are closed and there is no renewal of the air. The reason for this is that the walls and window, floor and ceiling absorb heat at a very considerable rate, and as it is not possible to raise their temperature sensibly, we may say that heating the air of a room is an operation like pouring water into a leaky vessel or trying to fill a bath when the waste plug is open. In this last case, in order to raise the level of the water at all, we must let in the water faster than it runs out, and the depth to which we can fill it depends on the ratio of the rates of inflow and outflow. So in the case of room heating, the demand for heat does not arise nearly so much from the heat capacity of the air itself as from the heat escape through the walls and windows.

Some curves, taken by Mr. A. R. Wolff, and kindly supplied to me by Mr. Huntley, the engineer of the Dowsing Radiant Heat Company, show in a remarkable manner the great loss of heat in ordinary houses through windows, thin walls, and skylights, and the immense advantages of double windows and walls (see Fig. 44). If our houses were only constructed on scientific principles so as to be heat tight, or at least less diathermous than they are at present, we should be astonished to find how little energy expenditure would keep us warm. The house of the future will have double walls, double windows, no chimneys, ventilation by electric fans, the incoming air heated electrically, and all the cooking and warming provided without any form of combustion or necessity for chimneys requiring constant sweeping. As constructed at present, however, experience shows that a rate of supply of electric energy equal to one watt for every cubic foot of air in a room will in general maintain it at a comfortable temperature in winter.

Hence, in the case of the room of 2,500 cubic feet capacity it would require at least 2·0 kelvins per hour or 2 kilowatts to be supplied to it to keep it warm in winter by electric heating. This is equivalent to a complete renewal of the air every 2½ hours. Since electric heating does not vitiate the air, and does not require any chimney, the ideal method of heating and ventilating a room would be to exhaust or draw out the vitiated air and heat the incoming air at the point where it is drawn in. It is clear, however, that nothing could be more unscientific than the ordinary system of room warming by gas or coal fires. The greater part of the heat goes up the chimney with the products of combustion. The incoming air is not warmed, but makes draughts along the floor, and the utmost that can be said is that the fire looks cheerful and ventilates the room.

Experience shows that a gas stove, as usually employed, suitable for warming a room of about 2,000–2,500 cubic feet, takes 50 cubic feet of gas per hour. Now, this amount of gas contains about 25,000 B.Th.U. total calorific energy, equivalent to about 8·0 kelvins. Hence, since about 2·0 kelvins per hour supplied to electric radiators will warm the room at the same rate, the average gas fire may be sending up the chimney energy equal to 6 kelvins per hour. Hence, 75 per cent. of the available heat may pass up the chimney with the products of combustion, and 100 cubic feet of fresh air

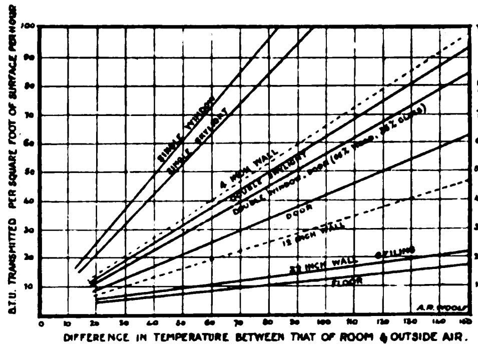

FIG. 44.—CURVES SHOWING THE LOSS OF HEAT IN B.TH.U. PER SQUARE FOOT THROUGH VARIOUS SURFACES. (A. R. WOLFF.)

has to be drawn in merely to burn the gas. As only 0·5 kelvin is required to heat the air itself from 32° F. to 65° F., the true efficiency of the gas fire can only be determined when we know how many hours' burning it would require to bring air in the room up to 65° F., and keep it at that temperature.

Electric room heating may be conducted by several kinds of heater—viz. (1) the luminous radiator; (2) the non-luminous radiator or convector; (3) the electroyl or hot-oil radiator; (4) the combined luminous and convector heater.

The luminous radiator consists in one form of two, three, or four cylindrical incandescent lamps, preferably carbon filament set in a reflecting hood with ornamental frame (see Fig. 43). The luminous radiation heats the bulbs and surrounding objects, and so warms

the air in contact with them. The second type of heater is the non-luminous convector,

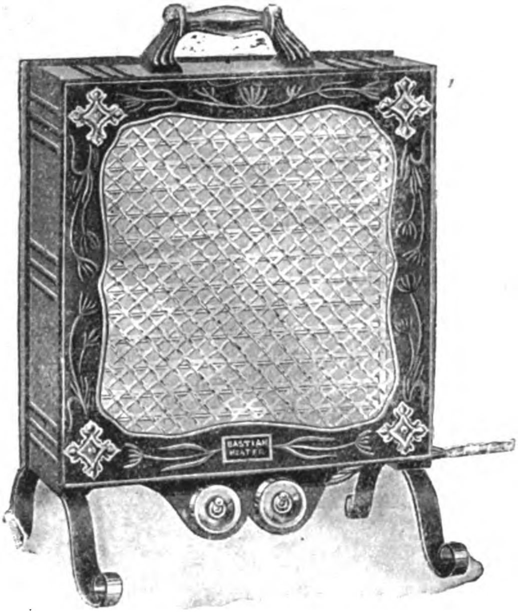

FIG. 45.—ELECTRIC CONVECTOR, OR NON-LUMINOUS ELECTRIC HEATER.

in which some kind of resistance wire is used to heat electrically a metal radiator with large surface (see Figs. 45 and 47).

The ordinary custom of placing a luminous radiator in the fire-grate to imitate a fire is entirely wrong. The air heated by contact with the radiator then mostly goes up the chimney instead of filling the room. The radiator or convector should be placed near the door so as to heat the incoming fresh air. Properly speaking, the fresh air should come in by special openings, over which the electric heater is placed, and the foul air should be removed by electric fans or Tobin's tubes (see Fig. 46, which shows such an electrical heater for heating incoming air, made by Messrs. Purcell and Nobbs). Moreover, the heaters should not be concentrated in one place. A room 16 ft. × 16 ft. × 10 ft. should have four radiators placed as far apart as possible, and not placed in the fireplace. In this manner distributed sources of heat tend to produce a uniform temperature of the air just as distributed lamps produce more uniform illumination. A system of luminous heating has been introduced by Mr. Bastian, in which spiral wires of a nickel alloy are enclosed in quartz tubes and heated to incandescence by the current. The quartz is quite transparent to non-luminous as well as luminous heat, and also serves as a mechanical support for the spiral.

In making a convector there should be two or three switches so introduced that the amount of heat generated can be varied. Thus, for instance, in heating a room (say) of 2,000 cubic feet the heater might be full on for one hour and then for eight hours at half-heat, using, say, 5 units in all.

The third type of heater is the low temperature electroyl radiator of Messrs. Purcell and Nobbs, in which the heat generated in a resistance wire is used to heat oil in which the wire is immersed, and the temperature maintained at 150° or 200° F. This type of electric heater is suitable for large rooms, and it is possible to have a luminous radiator, say, in one position so as to give a cheerful glow and non-luminous radiators in other parts of the room. The non-luminous radiators are made in various forms, suitable for heating ships' cabins, railway carriages, and offices. The relative advantages and disadvantages of these various kinds of electric heaters for room warming have been much discussed. The luminous radiators send out their

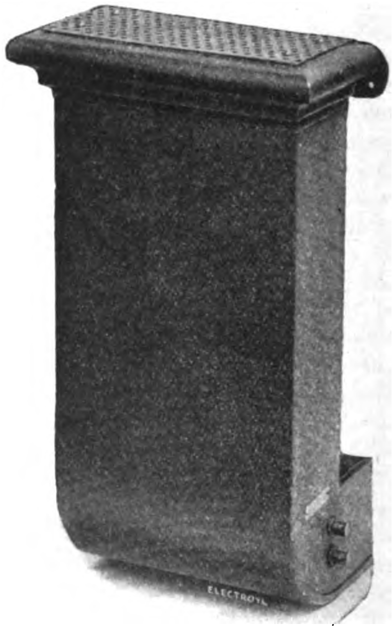

FIG. 46. ELECTROYL HEATER.
(Electric Tobin's Tube for heating the incoming air of a room.)

heat chiefly in a horizontal direction. The non-luminous, or convector heater is especially valuable in that it can be placed under windows

or skylights, and used to prevent down-draughts of cold air. Some results of experiments in room-heating by various electric methods are embodied in the curves shown in Fig. 48,

Fig. 47.—Electric Convector, or Non-Luminous Heater of Purcell and Nobbs.

supplied to me by the Dowsing Radiant Heat Company.

From a sanitary point of view electric heating is everything that can be desired. The glow-lamp heaters are suitable for occasional use, but require some outlay on lamp or spiral renewals. An excellent plan is to combine the luminous and non-luminous systems, ventilating the room by an electric fan, exhausting the air from the room at a point rather above the middle of the room, and then arranging three non-luminous heaters round the room, and a fourth luminous one for appearance.

As regards cost I have made some experiments in my own home on the relative cost of coal, gas, and electricity as heating agents.

Taking a room about 14 ft. × 20 ft. × 9 ft., having about 2,500 cubic feet capacity, I find that if a coal fire is kept running all day, say, for twelve or fourteen hours, it will use about 40 lbs. of coal per day, or $\frac{1}{8}$ ton per week. At 28*s.* this will cost 3*s.* 6*d.* per week, or $\frac{1}{2}$*d.* per hour for coal only, exclusive of wood or lighters, labour, and chimney sweeping.

I find that a gas fire of a good kind suitable for warming such a room takes 45 cubic feet per hour, and at 2*s.* 6*d.* per thousand the cost is $1\frac{1}{2}$*d.* per hour, or 7*s.* per week, running eight hours a day. As a matter of fact, such a gas fire will really cost somewhat less, because in the generality of cases it can be put out for some hours in the day without inconvenience and lit again at a moment's notice.

To do the same heating by an electric convector with electric energy supplied at 1*d.* per kelvin will cost about 2*d.* per hour, or about 9*s.* per week. Hence even at 1*d.* per unit it is not to be denied that electric room heating costs more than coal, but not much more than gas, whilst it has unquestionable advantages over either. When a sufficient demand springs up for electric energy for heating to enable the price to be lowered to $\frac{1}{2}$*d.* per kelvin, it will prove a most formidable competitor to both the older forms of heating, and in time will no doubt replace them both. Even now there is a large demand for electric radiators and convectors for heating ships' cabins and saloons, motor-houses, small offices, bedrooms, and any places where flame-heating cannot be used on account of danger of explosions. The present hindrances to its progress are, first, the want of proper electric heating wires in private houses. Electric heating circuits must be run to convenient points on the wainscot of kitchens, sitting-rooms, and bedrooms with appropriately placed fuses and switches. Then, in the next place, there must be a wider diffusion of the knowledge of how to use electric heating to the best advantages. Cheaper and more substantial appliances, both for cooking and room heating, must be placed on the market, and lastly the price per unit for electric energy for

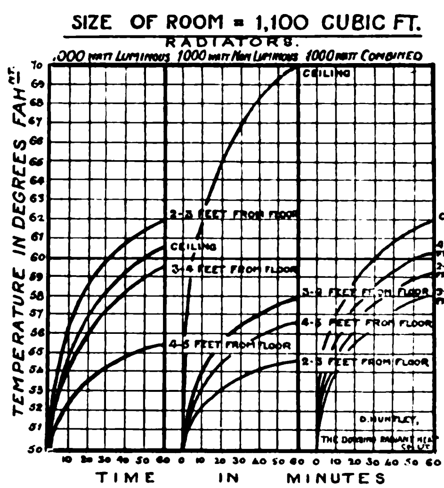

Fig. 48.

heating must come down to $\frac{1}{2}$d. Even at the present rates the advantages of electric cooking have only to be more widely known to be better appreciated, and it is not necessary to wait for

the perfection of electric room-heating before adopting it for cooking. The chief difficulty at present is the wiring problem and the absence of experience. But these obstacles can only be removed by degrees. The demand makes the supply, but the supply can only come from demand. Nevertheless, I have the firmest faith in the future of electric heating, not merely in the workshop and factory, in large metallurgical operations or mechanical arts, but in its home application in cooking, water heating, and room warming, giving us not only light and power, but the most perfect, cleanly, and convenient source of heat to meet all the demands of domestic life and serving to reduce the difficulties of monotonous but necessary domestic labours, which are not likely to be diminished in any other way.

TRAMWAYS AT MILAN.

The tramway system at Milan has developed of late years to an extent which no one could have believed thirty years ago. It was not until the year following the Exhibition held in that city in 1881, that the first lines worked by horses were opened. During that year (1882) the total number of passengers carried was 12½ millions, which was nearly doubled in the first five years, and trebled in the next ten, being:—

1886	24,012,817	passengers carried.
1896	35,548,801	" "

A further impulse was given in 1897 by the introduction of electric traction, when the network of tramlines was considerably extended, and the number of passengers carried, increased by 4,200,000, was:—

1897	39,748,801	passengers carried.
1898	44,548,801	" "
1899	57,740,801	" "

Since then a steady increase has been observed, partly due to the issue of workmen's tickets at a charge of only five cents in the early morning, and cheap fares generally. The opening of new lines, and the Exhibition of 1906, gave a further impetus to the popularity of the tramways. This was followed by a decrease in 1907; but since then the increase in the number of passengers has been steady:—

1904	86,634,059	passengers carried.
1905	94,384,365	" "
1906*	121,128,795	" "
1907	109,565,790	" "
1908	125,151,507	" "
1909	132,983,726	" "
1910	141,679,631	" "

In 1882 the average number of journeys made per head of population was only 32, as compared with 229 per head during 1910.

* Exhibition year.

The length of the lines of tramway on January 1st of each year was as follows:—

	Metres.	English Miles.	
1899	61,981	= 38·4	About one-sixth of total length of the streets of Milan, which was 336,610 metres (208 English miles).
1902	74,970	= 46·5	
1905	86,363	= 53·6	
1911	121,178	= 75·2	About one-quarter total length of streets, which are 509,282 metres (316·2 English miles).

THE MANUFACTURE OF JIPPI-JAPPA HATS IN JAMAICA.

What are generally known as "Panama" hats are not made in Panama at all, but chiefly in South America, especially in Colombia and Ecuador, and to some extent in several Central American States. The manufacture of these hats is an important industry in Ecuador, from which they were exported to the value of £250,000 in a recent year. In these countries the price of the hats usually ranges from two shillings to a guinea, but in Honduras some hats are made which sell for £5 each, and in Ecuador a kind called "Especiales" is made, requiring months of work to finish a single hat, which may sell there for £20 or even more. All grades of these hats are made from the leaves of a palm plant (*Carludovica palmata*), called locally in various countries Jippi-Jappa, from the canton of that name in the province of Manabi on the coast of Ecuador, where the finest of these hats are manufactured. The plant from which hats are made in Jamaica is said by some authorities to be exactly the same as that used in Colombia and Ecuador, but by others it is called Carludovica Jamaicensis, to indicate that there is a slight difference in the plants. The first hat of this kind manufactured in Jamaica was made in 1839 or 1840 by a Spaniard, who recognised the plant growing along the Cassava River as the same as that from which hats were manufactured in South America. In 1844, at a colonial exhibition at Spanish Town, the former capital of Jamaica, a prize of £20 was awarded for a hat of this sort made in the island. The making of these hats grew into so large an industry before the earthquake in 1907, owing somewhat to the purchases made by tourists, that a school was established in Kingston to instruct girls in the art. According to the United States Consul at Port Antonio, the plant which furnishes the material for the hats is a bushy palm growing in clusters along rivers and in damp places. Just before the long sheath or spathe which encloses the palm-leaf expands, it is cut off, the narrow outer blades on two sides are stripped off, the remaining portion is divided lengthwise into halves, and then, by sticking a pin or knife-blade through each half, the edge of the blades is split off on each

side, leaving a narrow strip of uniform width in the middle of the blades, the width being determined by the quality of the hat to be made, as the narrower the strips the finer the hat. These strips, still fastened to the stems, are boiled in water (salt and lime-juice being sometimes added) for half an hour and then dried in the sun. As they dry they shrivel up into a round, compact form, when the material, now ready for the hat-maker, is called "straw." It usually requires from twenty to thirty spathes or buds, which are twenty-five to thirty inches long, to furnish enough straw for an ordinary hat, the number varying with the size and quality of the hats. These hats are plaited or woven in one piece, the work being done chiefly by women and girls, although it provides occupation also for men in rainy weather, or whenever they have no outdoor labour to perform. It takes two to three days to make an ordinary hat, and ten to fifteen days to make a fine one. While the finer hats are being plaited, the straw is kept wet. When the plaiting is done the hat is washed and dressed, and then blocked and dried in the sun. After being worn, it may be washed and blocked again and again. The best of these hats can scarcely be distinguished from the so-called "Panama" hats, and their wearing quality is very good. There are no statistics to show the number of hats manufactured annually, but it is estimated to be between 50,000 and 100,000. The number could be largely increased, as besides the regular makers there are 460 girls who have recently been taught the art in the schools provided by the Agricultural Society of Jamaica. As two gold medals were awarded for exhibits of these hats at the recent Toronto Exhibition, and as it is announced that two Canadian firms have made arrangements to handle Jamaica hats on a large scale, this industry is likely to enjoy renewed prosperity.

CULTIVATION OF SUGAR BEET IN EUROPE.

The figures given below show the areas of land growing sugar beet in Europe at the present time as compared with those under the same cultivation last year.

In all these countries, with the exception of France, Belgium, Sweden and Roumania, the areas cultivated with sugar beet have increased this year by 181,677 hectares (448,742 English acres), or rather more than 9 per cent. over those of 1910. This is particularly noticeable in Russia, where the increase is nearly 18 per cent.

It is much to be regretted that England does not figure in this list, and that British farmers, in these times of agricultural depression (with perhaps a few exceptions), should be so backward in taking up a cultivation which the author of the paper on "Sugar-Beet Factories," recently read

	Areas in 1911.		Areas in 1910.		Percentage + or − in 1911.

before the Royal Society of Arts, termed "the life and soul, agriculturally speaking, of the north of France and Belgium." *

HOME INDUSTRIES.

An Industrial Judge.—The suggestion put forward by the President of the Master Cotton Spinners' Association, in a letter addressed to the Lord Mayor of Manchester—that a special department should be created with an advisory board composed of well-known men of the widest experience, representing both capital and labour, to whom disputes might be referred before the stage of a lock-out or a strike is reached, and over which an industrial judge, holding office permanently and independently of party politics, would preside—will be helped by the reply of the Prime Minister to a question put to him upon the matter. Mr. Asquith promised the support of the Government to "any feasible and properly-supported plan which might tend to prevent or shorten industrial warfare." There can be no difference of opinion as to the desirability of working to this end; the difficulty, of course, lies in devising a workable plan. The labour leaders appear inclined to support Sir Charles Macara's proposal, and Mr. Tom Fox, the Secretary of the British Labour Amalgamation and Lancashire and Cheshire Federation of Trades Councils, has given it as his opinion that "the great bulk of trade-union men would hail with very great satisfaction the establishment of such a court as Sir Charles Macara indicates." It would, of course, be well for both sides if such a scheme could be brought into operation. If successful, it would leave no bad blood as in many settlements made after a strike. But it is objected that it would be almost impossible to get a man with the necessary experience to act as industrial judge. How many outside men are there, for example, who understand the cotton trade? But as Mr. Thomas Ashlet, the Secretary of the Operative Spinners' Association, and one of the oldest trade-union leaders in the country, has pointed out, the judge might be appointed to act as the stipendiary magistrate does in certain cases, say in the Board of Trade shipping cases, where he has nautical and engineering assessors to assist him in technical details. The proposed judge in labour disputes, who might be an official of the Board of Trade like Mr. Askwith, or who might be appointed by the Board of Trade, could have a number of experienced men in all trades to assist him—to act as assessors, or to act like a jury. Then comes the question, should reference to such a tribunal be compulsory, and its findings final? Of course, if there was compulsion for one side there would have to be compulsion for the other—compulsion for both employer and employed. It may be that without compulsion the court would in time win the public confidence to such a degree that disputants would naturally turn to it for the settlement of their differences, but, human nature being what it is, it might also be otherwise. But at present Sir Charles Macara's proposal is little more than a suggestion. The character of the tribunal, and the powers to be conferred upon it, will invite and require full discussion before Parliament can be asked to move in the matter. Meantime, the conference to be convened by the Lord Mayor of Manchester should help to educate public opinion, and it will be a happy day for the country if discussion convinces those primarily concerned that the lock-out and the strike may be prevented by the establishment of some such tribunal for the settlement of industrial disputes as that suggested by Sir Charles Macara.

The Canadian Plan.—In considering this question, it may not be out of place to note what has been effected in Canada. In that country much good has been done by the Industrial Disputes Investigation Act. This Act prevents any strike or lock-out taking place before the matter in dispute has been considered by a board of arbitration. The dispute can be brought to early arbitration at the instance of either party, or of the Government alone. The arbitration board consists of one representative appointed by the employers, one appointed by the workmen, and a third appointed by the other two. When the board has made its decision no steps are taken to enforce it, and the parties are at liberty to proceed with a strike or lock-out if they think good. But, as a rule, the parties abide by the verdict, which usually has the irresistible weight of public opinion behind it. The Canadian Goverment states that out of 110 labour disputes that have occurred since the Act came into force in 1907, not more than ten have culminated in a strike or lock-out. The operation of the Act is highly praised in Canada.

Insurance and the Cotton Industry.—Attention was directed in these Notes last week to the excessive contributions asked from spinners and operatives by the Insurance Bill, and it was pointed out that the levy demanded from employer and employed was much in excess of the benefit offered. Since then a deputation of cotton employers has waited upon Mr. Lloyd George, and urged that the contributions demanded from them and their operatives are out of all proportion to the benefits, and that they are really helping to build up unnecessarily large reserves. Mr. Lloyd George reminded the deputation that the rates of contribution must not be judged wholly by the extent of the benefit received at the time when they are being paid; but this is not a complete justification for the rates themselves. The case for the spinners was put very forcibly by Mr. John Smethurst (Secretary of the Cotton Spinners' Federation), who has had information from thirty-three firms as to the working of the levy. These firms employ 5,782 people. The joint contributions would amount to

* *Journal*, May 12th, p. 656.

£8,031 9*s.* 2*d.*, and the sickness experience pointed to a sick benefit of £1,183 10*s*. per year, leaving a balance of £6,847 19*s.* 2*d.* He argues, basing his opinion upon actuarial reports, that the contributions of the workpeople and employers in the cotton trade should each be reduced by one penny. This would mean a reduction in the revenue expected to be received under the Bill of £250,000 a year. The scheme was able to stand this, as employers' and workpeople's contributions in eight years would be £155,577,000, while various benefits and costs of administration would amount to £127,869,000, showing a balance of £27,708,000 derived from the joint contributions of the employers and operatives alone. The reduction which the proposal would entail would amount to £2,000,000, still leaving a balance of £25,708,000.

The Packing of Wool.—The present methods of packing wool and tops was the subject of considerable discussion at the meeting of the International Congress of Woolcombers, Dealers, and Spinners, just held at Roubaix. Serious complaints were made against the system now adopted in Australia and Buenos Ayres of shipping the raw material in jute bags. It is asserted that under these conditions a great amount of loose vegetable fibre from the packing material finds its way into the wool, and as it is almost impossible to remove it during the subsequent operations, great damage ensues, every particle showing up when the goods are dyed. It was proposed that wool-growers should be acquainted with the position and advised to pack their product in paper-lined bags. It was further resolved that woolcombers be advised to adopt more stringent supervision during their processes and to take more precautions in packing tops, in order that spinners may have every assistance in their attempts to obtain cleaner raw material than is at present the case.

Scottish Motor Spirit.—The Scottish mineral oil companies continue their efforts to obtain the removal of what they consider a serious grievance. They complain of hampering Revenue restrictions. It is stated that the dutiable spirit amounts to only 1 per cent. of the whole production of the companies, and that to obtain the duty, amounting in the aggregate to between £8,000 and £9,000 per annum, 10 per cent. of the companies' total products is distilled under Revenue supervision, with all the expense and inconvenience that that entails. Nine-tenths of the spirit so distilled is used for lighting, cleaning, and as a solvent, but before any user can receive delivery of the spirit without payment of the duty he must give certain undertakings and comply with elaborate regulations regarding permits and the keeping of books. Those restrictions are a disadvantage to Scottish shale naphtha when it comes into competition with benzol made from coal-tar and other spirits. Petroleum spirit, on the other hand, is distilled abroad without any such restrictions in manufacture, and is transported in tank steamers and pumped ashore, where it comes under Revenue control for the first time. The bulk of this spirit is used for motor fuel, but it competes in other directions also with shale spirit, generally for cleaning, and necessarily has a very decided advantage from this lower cost of production due in part to freedom from restriction during distillation.

The Milk Supply.—The Report of the Royal Commission on Tuberculosis scheduled animal infection as one cause of tuberculosis, and milk from tuberculous cows is the vehicle of the infection. Much of the milk supply of this country is tuberculous, and if it is to be purified new powers of inspection and regulation are necessary. The Dairies Bill, introduced in 1909, would have given these powers, and it is hoped that it will be reintroduced and carried this Session, though, having regard to the period of the year, that seems almost too much to hope for. The Bill provides for the registration and inspection of dairies and the prohibition of the sale of tuberculous milk from an infected dairy. It is on the model of many local acts already in force, and simply makes the precautions universal. It includes provisions for the isolation, and, if necessary, the slaughter of tuberculous cattle, with compensation where equity requires it. The public health is in pressing need of some such Bill.

GENERAL NOTES.

Early Fruit and Vegetables from Italy.—Efforts are being made by shippers in Naples and Palermo to obtain a subvention from the Italian Government, in order to establish a line of quick steamers from Naples, touching at Palermo, to London. These steamers, which would be specially designed for the conveyance of early fruit and vegetables from Southern Italy and Sicily for the London market, would be provided with every convenience for the rapid loading and discharge of their cargoes, and for carrying them to their destination in perfect condition.

Proposed Optical Convention, 1912.—An executive committee has been formed for the purpose of making arrangements for the holding of an Optical Convention and Exhibition of Optical and Allied Instruments in London, in the spring or summer of 1912. The proposal has grown out of the successful Optical Convention held in the year 1905. The Convention lasted for four days; many valuable papers were read; a collection of choice and interesting instruments was brought together for the purpose of the exhibition; and the volume of proceedings produced was of notable and permanent interest. It is thought that, after

an interval of seven years, the experiment may be repeated with an assured prospect of success. The executive committee was appointed in the early part of this year, and proceeded forthwith with the necessary work of getting together a guarantee fund to provide against the expenses incidental to the holding of the Convention. Their appeal, which down to the present time has not been publicly issued, but has been addressed only to the members of the committee and to their more private friends, has been so far successful that, with the assistance of two City companies, they have already secured guarantees to the extent of £600. They think themselves warranted in expecting that when their public appeal is made a further sum of £400 at the least will be forthcoming, and they count therefore upon being able to make their preliminary arrangements upon the basis of a guarantee fund of not less than £1,000.

TRADE IN MOROCCO.—In his report on the trade of Morocco just issued (No. 4,621 Annual Series), Mr. Vice-Consul Bristow refers to the difficulties which hamper the importation of foreign goods into Morocco, and says that the extreme unpunctuality with which it is the custom to meet payments is one of the principal. This unpunctuality is largely attributable to the fluctuations in the rate of exchange. The bills drawn on the importer by the foreign merchant are almost invariably drawn "payable at the sight rate of exchange," that is to say, the importer must meet them either by means of a cheque, payable in gold, or by a payment in currency equivalent at the rate of exchange of the day to the sum due in gold. In his turn the importer quotes in gold, and thus passes the risk of exchange on to the retailer. The latter, therefore, not only charges the consumer a price in currency calculated to provide him with a sufficient margin to cover this risk, but also very frequently delays his payments to the importer until the rate of exchange is, in his opinion, most favourable, and thus prevents the importer himself from meeting his liabilities at due date.

SCARCITY OF CINNAMON IN CEYLON.—With the extension of rubber and cocoanut cultivation in Ceylon, owners of cinnamon plantations in suitable localities have found it to their advantage to root out cinnamon, and plant either rubber or cocoanuts. It hardly pays the cinnamon planter to continue cultivation of the product at existing prices, and a good many of them have substituted the more remunerative products. This is especially noticeable in the southern province, where rubber is replacing cinnamon, and in the Negombo district, where cocoanut cultivation is being extended. As a result of all this, there is a scarcity of cinnamon in the market just now. To make good the deficiency in the European market, cassia bark, imported from China, is being used as a substitute. Cassia bark is said to have a stronger and somewhat coarser flavour than cinnamon, and is coming to be much appreciated. According to the American Consul at Colombo, it is not improbable that it will swamp the cinnamon trade completely, if the cultivation of the latter is not encouraged. A rough estimate places the acreage of cinnamon cultivation in the island of Ceylon at 45,000 acres.

POTATO-ALCOHOL IN RUSSIA.—In the alcohol distilling industry of Russia potatoes are annually increasing in importance, the alcohol produced therefrom exceeding that from all other sources. Apart from the large quantities of potatoes purchased every year by the factories from peasant producers and estate owners, whenever they may have a surplus which they cannot more profitably dispose of, there are large plantations devoted solely to the production of potatoes for distilling purposes, and there is also a tendency to increase these plantations. The potato crop for 1910 was greatly in excess of that of the previous year, which was also a good one, and the quality of the tubers was in most districts better than in 1909. It is generally supposed that the climate of Russia is favourable for the production of potatoes in vast quantities, and that with the aid of fertilisers their production can be increased to meet all demands of distillation, the production of denatured spirits for industrial and illuminating purposes now being only in its infancy.

THE PRODUCTION OF MONTAN WAX IN GERMANY. —Montan wax, which in other words is miner's or bituminous wax, is exported in considerable quantities from Germany and, according to the American Consul at Hamburg, is much sought after by European, and particularly American, manufacturers. The material is obtained by the distillation of the bitumen of sulphurous brown coal, extracted by benzine, by means of superheated steam. Pure montan wax has a melting-point of 80° C., and it is an excellent substitute for ceresine, deriving its great value from its high melting-point, a quality much appreciated in the candle manufacturing industry. The utilisation of this material at the same time facilitates the working of deposits of sulphurous coal. German exports of montan-wax-bitumen and raw ozokerite in 1909 amounted to 1,289 tons, valued at £40,000, of which 147 tons went to Great Britain and 851 tons to the United States.

ANCIENT BRASSES AT EARL'S COURT. — The Queen's Palace at Earl's Court contains, among other exhibits, an interesting show, arranged by Messrs. Gawthorp and Sons, illustrative of ancient brasses. One rubbing represents the Abbot Delamere of St. Albans; the University Museum of Cambridge has lent some palimpsest fragments, and the Archæological Society of Northampton has several effigies ranging in date from 1400 to 1550. In addition to the metal work, there are some fragments of very fine fifteenth century glass, including a badge of Catherine of Arragon.

NOTICE.

INDIAN SECTION COMMITTEE.

A meeting of the Committee of the Indian Section was held on Tuesday afternoon, the 1st inst. Present:—Sir William Lee-Warner, G.C.S.I. (Chairman of the Committee), Lord Sanderson, G.C.B. (Chairman of the Council), Sir Arundel T. Arundel, K.C.S.I., Sir M. M. Bhownaggree, K.C.I.E., Sir George Birdwood, K.C.I.E., C.S.I., LL.D., M.D., William Coldstream, B.A., Sir Steyning William Edgerley, K.C.V.O., C.I.E., James Fairbairn Finlay, C.S.I., Sir Frederic W. R. Fryer, K.C.S.I., R. A. Leslie Moore, Sir Patrick Playfair, C.I.E., Sir James Wilson, K.C.S.I., with S. Digby, C.I.E. (Secretary of the Section).

ANCIENT INDIA'S COMMERCIAL RELATIONS.*

By Jogindra Nath Samaddar, B.A., F.R.Hist.S.

I.

In the unfortunate adventure of Bhuga, son of Tugra in the Rigveda, a distinct reference is made to the fact that the singers of the Vedic hymns had heard of voyages in seas where no trace of land could be found. Mr. R. C. Dutt, in his "Civilisation in Ancient India," aptly says: "There are distinct references to voyages by sea, though of course the words used may mean rivers only." The shipwreck of Bhuga and his deliverance by the Asvins is constantly alluded to (i. 116, 3 and 4). In i. 25–7 the god Varuna [Greek Ouranos, "Uranus"] is said to know the paths of the birds through the sky and the paths of the ships over the sea. In iv. 55–6, the poet refers to the "people who, desirous to acquire wealth, pray to the sea before undertaking a voyage"; while in vii. 88, 3, Vasistha says: "When Varuna and I went on a boat and took it out to sea, I lived in the boat floating on the water and was happy in it, rocking gracefully on the waves." The Rigveda thus contains allusions which stand as a witness within India to our forefathers having been a sea-faring as well as maritime people.

Again in Manu, chapter viii. section 157, we find that interest on money lent on transport risks is to be fixed by "men well acquainted with sea voyages, or journeys by land." The historian, Mountstuart Elphinstone, is of opinion that "as the word used in the original for sea is not applicable to any inland waters, the fact may be considered as established that the Hindus navigated the ocean as early as the age of the Code."

If we place the age of Manu 900 years B.C., we shall see that even before this there were commercial relations between the East and the West. The earliest trade was by the overland route, followed by the Phœnicians along the caravan road by which they are supposed to have originally emigrated between 3000 and 2500 B.C., from the shores of the Persian Gulf to the narrow Mediterranean coast of Syria. "By it also the Eastern arts of pottery, ivory-turning, glass-making, enamelling, and wood-carving, were at last carried into the remotest recesses of Germany and Scandinavia, and profoundly influenced the primitive civilisations of those countries. The appearance among the prehistoric remains of Switzerland and Denmark of arms and implements of bronze, in succession to spear and arrow-heads of flint, generally affirmed to be due to the displacement of the primeval savage tribes of the West by the immigration of new races of a higher civilisation from the East, probably rather marks the age

* In connection with this subject, it may be worth while to refer readers of the *Journal* to the classical paper on the "Quest and Early European Settlement of India," read before the Indian Section by Sir George Birdwood (see *Journal*, Vol. xxvii., p. 192, February 7th, 1879). It takes up the history of Indian trade and commerce at the point where Mr. Samaddar leaves it.

of the earliest Phœnician intercourse with Europe; and when gradually the trade between the East and West took the routes by the Persian Gulf and the Red Sea, it still remained in the hands of the Phœnicians."

Mr. Elphinstone has also admitted that even before the age of Manu, there was intercourse with the Mediterranean countries. It cannot, however, be exactly said whether the route followed was an overland one or by sea.

In truth, the rich commodities of India had not only to be fought for in days of yore—as they are now—by all the commercial nations of ancient times, but these inspired them with a keen desire to open, as far as possible, even more and more direct channels for their transport. Among those nations the Jews stood supreme. The valuable commodities of India figured greatly in the Durbar of King Solomon. We will quote here some of the passages in the Old Testament where we find reference to these. First, in the thirty-seventh chapter of Genesis, the brethren of Joseph, when about to leave him to perish, saw a company of Ishmaelite or Midianite merchants approach, to whom they resolved to sell their brother as a slave. Dr. Vincent remarks on this passage: "Here, upon opening the oldest history in the world, we find the Ishmaelites from Gilead conducting a caravan of camels loaded with the spices of India."

Again: "And Hiram sent in the navy his servants, shipmen that had knowledge of the sea, with the servants of Solomon. And they came to Ophir, and fetched from thence gold, four hundred and twenty talents, and brought it to King Solomon" (1 Kings ix. 27, 28).

"And the navy also of Hiram, that brought gold from Ophir, brought in from Ophir great plenty of almug trees, and precious stones" (1 Kings x. 11). "Besides that he had of the merchantmen, and of all the traffick of the spice merchants, and of all the kings of Arabia, and of the governor of the country" (1 Kings x. 15). "For the king had at sea a navy of Tarshish with the navy of Hiram: Once in three years came the navy of Tarshish, bringing gold and silver, ivory and apes and peacocks" (1 Kings x. 22).

Now, the precious stones of King Hiram's cargo still lie in the hills to the west of Ajmere, rich in garnets, amethysts, chrysolites, and metals; and also in the hills of Guzerat, where agates, mocha stones and carnelians are found below the surface of the soil. Nard and Bdellium, Calamus and Cassia, were all products of India, and the Cassia of Scripture is the tamal of Sanskrit literature. Queen Esther's white and blue hangings at Persepolis were and are attributed to India, and the word *karpas*, as used in the book of Esther, is the Sanskrit name *karpasa* for the cotton plant. The Hebrew words are evidently of Indian origin; thus *kof*, "ape," is the Sanskrit word "kapi"; *thukki*, a peacock, is probably the Tamil *tokei*, and Shenhabbim, "ivory," is explained by Gesenius as a contraction for *Shen-a-hibbim*, the latter part being the Sanskrit word *ibha*, an elephant, with the Hebrew article prefixed. The names of products, as Professor Lassen remarks, are not the only Sanskrit words early introduced into Hebrew by the means of trade, and the inference is that the "Ophir" of Scripture must have been in India, and probably on the Malabar coast. In all probability, Indian navigators shipped the goods from the Indus to some part to the south of Bombay, whence they were fetched by the Arabs or Phœnicians.

When Nebuchadnezzar destroyed the Jewish Government *circa* 588 B.C., some of the Jewish merchants accompanied him to Babylon, and carried on their commercial pursuits there. Nebuchadnezzar was a patron of commerce, and the Jewish merchants became very rich, as the constant intercourse which subsisted at this period between Babylon and the principal parts of Hindustan afforded them the means of participating in the lucrative commerce of India. Thus a close connection grew up between Assyria and Persia and Syria, and the Jewish merchants settled in some of the towns of these countries and carried on trade with the Malabar coast. It is possible that constant intercourse made some of these men settle in Malabar. No definite date can be assigned when they began to settle in Malabar, but from the copper-plates which are still available in the synagogues at Malabar on which there are inscriptions, we can surmise that they came about the close of the reign of Nebuchadnezzar—that is, some 600 years before the birth of Christ. From the inscriptions, it transpires that the Jewish merchants were well received by the Zamorin, that in numerical strength they exceeded two thousand, and could freely indulge in the exercise of their religion. They bought land and built a synagogue there, and appointed one of themselves to govern their colony.

From Homer, we come to know that the celebrated bed of King Menelaus, the brother of Agamemnon, was carved from the tusks of Indian elephants. The genealogy of the words for ivory and elephant is said to prove that

Greece got ivory from India. There was no word in Greek for elephant, and when Herodotus, "the father of History," saw an elephant he called it ivory, using the Sanskrit-derived word by which the tusks were known in commerce. From the references in Greek literature we are led to suppose that our ancestors confined themselves to river-borne trade. But these Grecian authors admit that shipbuilding was in vogue. Arrian, in speaking of the castes of India says: "Of this class (*i.e.*, the fourth) are the shipbuilders and the sailors, as many as navigate the river." Thus we find a reference to the "rivers," but not to the "sea." Nearchus, the naval commander of Alexander the Great, did not perceive, save fishing-boats, any large-sized boats from the Indus to the Euphrates. Even in the Indus he did not find many boats. The ships of Alexander he had to prepare with his own men, and to man them with men from the shores of the Mediterranean Sea. We shall discuss this statement of Nearchus as we proceed.

Whatever might or might not be the effects of Alexander's invasion, there is no denying the fact that the invasion opened up new trade routes and vistas. Mr. Beveridge truly remarks: "Such exploits, once deemed the only avenues of fame, are now judged more easily. Still it is impossible to deny that conquerors were often in early times pioneers of civilisation, commerce following peacefully along this bloody track and compensating for their devastation by the blessing which it diffused. Such was certainly the result of the Indian expedition of Alexander; and therefore, while reprobating the motives in which it originated, we cannot but rejoice that it was so overruled by Providence as to be productive of most important valuable results."

Exactly so. That a closer commercial connection grew up between India and the West is evidenced by the fact of the coming of Megasthenes; and of Bindusara, the son and successor of Chandragupta [Sandracottus] asking for figs and raisin wine, and requesting King Antiochus "to buy and send him a professor!" Megasthenes also speaks of the ports of India; while a contemporary manuscript, recently brought to light and translated into English by Pundit R. Shamshastry, Librarian of the Government Oriental Library, Mysore, and into Bengali by the writer of this article, lays down precise rules for the conduct of the trade between India and the West. In Book II., chapter xvi., the duties of the superintendent of commerce are laid down, in which the following passage occurs:

"The superintendent shall show favour to those who import foreign merchandise: Mariners (*navika*) and merchants who import foreign merchandise, shall be favoured with remission of trade taxes so that they may derive some profit. Foreigners importing merchandise shall be exempted from being sued for debts unless they are (local) association and partners."

As regards the sale of the king's merchandise, in foreign countries, Chanakya, also known by the name of Kautilya, lays down the following rule. The passage is a long one, but as the book is a rare one we crave indulgence of the readers to reproduce it fully.

"Having ascertained the value of the local produce as compared with that of foreign produce that can be obtained in barter, the superintendent will find out whether there is any margin left for profit after meeting the payments (to the foreign king) such as the toll, road-cess, etc., etc., and the portion of merchandise payable to the foreign king. If no profit can be realised by selling the local produce in foreign countries, he has to consider whether any local produce can be profitably bartered for any foreign produce. Or he may take his merchandise to other countries through rivers. Having gathered information as to the transaction in commercial towns along the banks of rivers, he shall transport his merchandise to profitable markets."

Again, in chapter xxviii. the superintendent of ships is enjoined "to examine the accounts relating to navigation not only on oceans and mouths of rivers, but also on lakes, natural or artificial, and rivers in the vicinity, etc." In the fourth book, second chapter, the superintendent of commerce is directed to fix a profit of 5 per cent. over and above the fixed price of local commodities and 10 per cent. on foreign produce.

We can surmise that Kautilya would not have indulged in these minute instructions had not commerce been in a flourishing state. In fact, we come across the names of many ports on the Son and the Ganges, and even now traces are found of a stone embankment on the River Son. As things really stood, we are tempted to agree with the view of Mr. Elphinstone that "it is probable that at the same time when Nearchus saw little sign of commerce on the Indus, the Ganges may have been covered with boats."

Turning now to the second century before Christ, we see from Agatharchides that there was commercial connection with the west coast of India and the countries to the West, and this author expressly mentions that ships went from India to the ports of Sabaea. Passing

over two centuries, we obtain clear accounts of this trade by reading "The Periplus of the Erythraean Sea." The author has left us a clear description of the coast of India, from the Indus round Cape Comorin to a point high up on the coast of Coromandel. We gather that the ships from India continued to cross the mouth of the Persian Gulf and from the shores of Arabia to the mouth of the Red Sea, and the Egyptian Greeks used to quit the coast soon after leaving the Red Sea, and then stretch across the Indian Ocean to the coast of Malabar The Periplus describes the Indians as actively engaged in the traffic on their own coast. "There were boats at the Indus to receive the cargoes of the ships which were unable to enter the river on account of the bar at its mouth; fishing boats were kept in employ near the opening of the Gulf of Cambay to pilot vessels coming to Baroach." Large vessels crossed the Bay of Bengal to the Ganges and Sumatra and Java. Thus we find in the histories of Java that a body of Hindus from Calinga went to Java possibly by the end of the first century B.C. From Fa-hian and Hiewn Tsang also we find that the Indians of those ages used to indulge in maritime enterprises.

II.

We referred in the first part of this article to the Phœnicians. There was always a close commercial connection with Syria and Egypt. The direct commercial relations with India and Syria ceased with the conquest of Syria by the Roman Emperor Aurelius. But the connection with Egypt and Greece *via* Alexandria was becoming closer day by day, and the Ptolemies gave great encouragement to commerce. The ancient history of the Egyptians says:

"Ptolemy II. (Philadelphus) thought it necessary to found a city on the western shore of the Red Sea, whence the ships were to sail. He accordingly built one on the Gulf called Immundus, and to this day "Foul Bay," and he gave it the name of his mother Berenice. The treasures of Arabia, India, Persia and Ethiopia, were landed, and from thence they were carried on camels to Coptos, where they were again shipped and brought down the Nile to Alexandria, which transmitted them to all the West in exchange for merchandise afterwards exported to the East."

Thirty years before the birth of Christ, when the Emperor Augustus conquered Egypt, this flourishing commerce fell into the hands of the Romans. The Romans were hitherto enjoying the luxuries of the East in a roundabout way, but now that the very emporium fell into their own hands they began to employ their wonted energy, with the result that a fleet was prepared for trading with the East and a closer commercial relation grew up between Rome and India. The spirit of adventure grew up day by day, and, forsaking the old circuitous route, they began to sail from the coast of the Babel-mandeb, and come direct to Malabar and Guzerat by sea. The mariner Hippaulans noticed the directions of the monsoon and began to sail by this way. The result was that the journey now took half the time than it used to take before.

From this time, till the fall of the Western Empire, there was constant exchange of commodities. Every year a fleet of 120 ships sailed from Myos Hormos and came to Mousiris Emporion and Bakarei on the Malabar coast, and thence sailed to Ceylon. Ceylon then was a great emporium, and merchants of Bengal, Orrisa and Karnat (the present Carnatic), used to come there and exchange commodities. The Romans used to buy our goods in exchange for gold and silver and having completed their purchases this fleet of 120 ships used to return home. Generally they left Ceylon in December or in January, and silk, muslin, spices and essences, as well as pearls and other valuable stones, used to leave our shores in this way. This exchange of Indian commodities for gold and silver is fully corroborated by Mr. Vincent Smith in his history of India (1st Edition, p. 337).

Roman gold coins of the early Empire have been discovered in such large quantities in Southern India that it is apparent that they served for the gold currency of the peninsula. Five coolie loads were found as late as in 1851 near Cannanore on the Malabar coast, mostly belonging to the mintage of Tiberius and Nero; and many other large loads of Roman coins, gold, silver and copper, have been discovered in various localities from time to time.

Mr. Vincent Smith truly remarks that "it is certain that the Pandya State, during the early centuries of the Christian Era, shared along with the Chera kingdom of Malabar a very remunerative trade with the Roman Empire." Pliny has justly said, in writing of the commercial relations with India, that "amidst the rude ignorance which characterised the Middle Ages in Europe, the commerce with India served to soften and instruct those nations who participated in it; and in modern times it fostered that spirit of enterprise which was destined to render navigation subservient to philosophy and knowledge,

by making the inhabitants of far distant countries acquainted with each other, and by familiarising their minds with the various habitudes and customs that diversify human life."

Even as late as A.D. 400 coins of Arcadius and Honorius of the smallest value have been found in considerable numbers at Madura, and suggestions have been made that there might have been even a Roman colony there. At anyrate, Rome and India were then in the closest ties of commercial friendship.

When the capital was removed to Constantinople in 324, the Western Empire declined, and the trade through Egypt and the Red Sea ceased altogether. The merchants of Alexandria were becoming too luxurious day by day, and simultaneously the craving for commerce came on the Arabs. The Arabs were already proficient in navigation, and the energy which they received now through the propagation of Islamism, infused a new spirit amongst this hardy nation. Actuated by an irresistible impulse to convert all, they were eager to go to fresh lands to propagate their new religion. As an outcome, commercial relations were established by trading. A fleet of ships expressly manned to trade with India began to come year after year, and the Arabians began to settle on the coast of Malabar. It is even said that to smooth their commercial way they converted the Zamorin, who was induced by the Dervishes to go on a pilgrimage to Mecca. Thus the Arabian commerce thrived. The Egyptians, forgetting their own interest, and being able to procure Indian commodities at less trouble, though at greater cost, through the Arabians and Persians, refrained altogether from continuing their relations with the Indian ports.

The Persians were at first averse from maritime enterprise, but, learning from Indian merchants the route from the Persian Gulf to the Malabar coast, they began to send ships to different ports in the Malabar coast. They either used to exchange their own commodities or buy Indian commodities with money. The time taken up for a single voyage was at an average ten weeks. When the goods reached the Euphrates, they were carried by boats to Assyria and Mesopotamia, and, as the people of Constantinople could get Indian products without the risk and troubles incidental to adventurous voyages, the desire to indulge in commercial pursuit began to die in them.

It was for these reasons that the Persians and the Arabs made a monopoly of Indian commerce in the seventh century A.D., but, as the Persians possessed many natural advantages, they began to predominate over the Arabians, and soon the Persians altogether monopolised the silk trade of the East. As a war broke out between the Persian King and the Emperor of Constantinople, the China silk which used to reach Greece through Tartary was also stopped, and the Persians began to charge exorbitant rates for these silks. The Emperor Justinian tried to remedy this evil, but for a long time was unsuccessful. At last Providence found out a way. Two monks, who had come to China and India for preaching the Gospel, had seen the rearing of silkworms and the manufacture of silk. They, in the course of conversation with Justinian, spoke of this, and the Emperor urged on these monks to return and learn fully the art of manufacture of silk. They spent a few years in China, and, having learnt fully the art, took in a hollow cane a few worms and went back to Constantinople. These worms were placed on dung and, when hatched, were fed with mulberry leaves. The hopes of the Emperor were fulfilled, and manufactories were established in some of the Grecian islands. Thus the export of silk from China and India to Rome stopped altogether, but other commodities still found their market in Greece in the following centuries.

We have already said that the new religion of Mahomet invigorated and gave a new life to his followers. After the death of the Prophet, Omar conquered Persia and gave his religion to the Persians and established the Caliphate. With Persia the Indian trade also fell into the hands of the Mohammedans. The Caliph, in order to encourage commerce, established a port at Basora which became soon an important mart, and finding Indian trade very advantageous the Mohammedans intended to introduce Indian commodities into Syria. When Egypt and Syria fell into the hands of the Caliph, the Alexandrine merchants were prohibited from trading with Byzantine kindgoms, and as there was constant warfare with Mohammedans and the Greeks, the latter, as well as the Italians, were deprived of Indian commodities.

Those Roman monks who had carried silkworms in their canes knew that Amal and Archenzi (modern Archenzed) on the Oxus were also marts for Indian and Chinese goods. Some of the adventurous merchants of Constantinople sent their agents to these ports, and they managed to send commodities through the Caspian Sea and the River Cyrus. Here they were embarked and then conveyed by land to some distance, and thence again by the Black Sea, ultimately

reaching Constantinople. The Mohammedans at this time were very powerful. They established a colony at Malabar and had commercial relations with Bengal, Siam, and China. Greece and Rome viewed with great jealousy the rise of this Mohammedan power.

Venice had from the middle of the fifth century established commercial connection with Alexandria and Constantinople, and by the middle of the sixth century had imported silks from India and China. From the beginning of the ninth century spices, medicines, and silk of India used to reach the marts of Venice, which began to hoard wealth and to grow rich by this Indian commerce. At the end of the Crusades, amicable relations having been established between the Christians and the Mohammedans, the route through Egypt was reopened and thus commodities again began to reach the continent of Europe.

Even before Venice, Genoa had enjoyed to a small extent Indian commodities, and when Venice and Genoa were each thwarting the other, Florence was rising under the Medicis. Under the fostering care of the Medicis, the Florentines began to trade with the East and commerce thrived. When Egypt and Syria were conquered by Selim, Venice forsook her neighbours, and gradually, when Cyprus fell into her hands, she made a monopoly of the Eastern trade and Cyprus soon became an emporium. The fall of Constantinople ruined the Genoese trade with the East by the Black Sea, but the discovery of the passage to India by the Cape of Good Hope gradually undermined the Venetian trade by Alexandria.

The Portuguese were the first who explored the South Atlantic coasts of Africa, and by their discovery they opened up to the nations of Europe the sea-way through the Indian archipelago. We are all familiar with the subsequent events, and we need not go into them.

III.

We shall now discuss the routes which were followed by merchants in coming in and going out of India. By the overland route merchants could go to Bactria by the north-west passage. Thence they went to Balk, where they spent some time in marketing, and after that to Babylon, where Indian commodities were highly valued. From the shores of the Caspian Sea the goods were then despatched in ships, and after that, by a land route and the Black Sea, they reached the Mediterranean Sea. From Babylon they passed to Palmyra and thence to the Levant, where Indian commodities had a ready sale. Generally, European goods were exchanged for Arabian and Indian goods in these places. The route was an adventurous one, the commodities being generally borne by camels. As soon as the water route was discovered, this came to be abandoned.

When the Phœnicians were engaged in this profitable commerce they used to send goods to Tyre *via* certain ports on the Red Sea. This, too, was of considerable disadvantage. When they became possessed of Rioncula on the Mediterranean Sea, they used to carry Indian goods to the Red Sea, whence they were borne some distance by land, reshipped, and thus reached Tyre. Although goods had to be shipped over twice, this was found of greater advantage than the overland route. When Tyre was destroyed by Alexander in 322 B.C., Alexandria was founded by him, and as thus a fresh opening was made, for nearly eighteen centuries goods were despatched by this route. Alexander personally recommended this route, but he could not live long enough to carry out his projects. Immediately after his death, Ptolemy Lagos ascended the throne, and a lighthouse (which was then considered as one of the seven wonders of the world) was built by him at considerable expense. His son, Ptolemy Philadelphus, tried to cut a canal through the Isthmus of Suez, but, failing to do this, founded a town, as above stated, on the coast of the Red Sea.

As long as Egypt remained independent, this route was followed. European manufactures used to come to Berenice and thence were taken to the ports on the Arabian Sea and Persian Gulf, and so on to the Indus. The merchants did not confine themselves to the towns on the Indus, and in all probability all the ports of the coast line were also utilised. To make a monopoly of this lucrative trade, the kings of Egypt kept ready a strong fleet, both merchantmen and men-of-war. Even when the Romans conquered Egypt this route was followed.

From the Periplus we know that muslin, various kinds of chintz, silk threads, indigo and other colours, cinnamon and other spices, sugar, diamonds, pearls, steel, medicines, scents, and occasionally slave-girls, also were exported from India.

Many of the commodities mentioned in the Periplus formed, and form now, the staple exports of India. Sir George Birdwood in the *Journal of the Society of Arts*, February 7th, 1879, wrote that "the history of modern Europe, and emphatically of England, has been the

quest of the aromatic gum-resins and balsams and condiments and spices, of India and the Indian archipelago." Abbé Renaudot in his "Anciennes Relations des Indes et de la Chine" (1718), writing of two Arab merchants who travelled in the ninth and tenth centuries in India, says that India then exported tea, porcelain, spirits and rice.

Edrisi, the Nubian geographer, speaks of the fine threads of the Coromandel coast, chillies and spices of Malabar, camphor of Sumatra and lemons of Hyderabad (1099–1186). Benjamin of Tudela, travelling in India in the twelfth century, speaks of India's exporting silk cloth, pulses and spices. He also writes of cinnamon, ginger and other sorts of spices as found in abundance in South India. Ibou Batuta, the well-known traveller, writes of aloes, camphor, sandal-wood, jambolin, mangoes, oranges, some of which were exported. The Venetian nobleman, Marino Samito, came to the East some time early in the fourteenth century. He writes of various spices being exported from India. The Genoese traveller, Hieronimo di Santo Stefano, coming to India in the end of the fifteenth century, speaks of garnet, jacinth, cats'-eye, and various sorts of spices which had a ready market. Ludovico di Varthema wrote that 300 ships of other countries used in his time [16th century] to come to India. Lastly, the letter which the Zamorin of Calicut wrote to the King of Portugal clearly speaks of the export of India:—"Vasco de Gama, a nobleman of your household, has visited my kingdom and has given me great pleasure. In my kingdom, there is abundance of cinnamon, cloves, ginger, pepper and precious stones in great quantities. What I ask from thy country is gold, silver, coral and scarlet."

"Southern India had the good fortune to possess three precious commodities not procurable elsewhere, namely pepper, pearls and beryls. Pepper fetched an enormous price in the markets of Europe, and was so highly prized, that when Alaric the Goth levied his war indemnity from Rome in A.D. 409 his terms included the delivery of 3,000 pounds of pepper." In Gibbon, chapter xxxi., we find the following:—"Pepper was a favourite ingredient of the most expensive Roman cookery, and the best sort commonly sold for fifteen denarii, or ten shillings the pound."

The pearl fishery of the south is referred to by Mr. Sewel in the *Journal of the Royal Asiatic Society*, 1904. Mr. Vincent Smith in the admirable "History of India," also says: "The pearl fishery of the southern sea, which still is productive and valuable, had been worked for untold ages, and always attracted a crowd of foreign merchants. The mines of Padiyur in the Coimbator district were almost the only source known to the ancient world from which good beryls could be obtained and a few gems, more esteemed by both Indians and Romans."

In an article on "Roman Coins found in India," Mr. Sewel, in the *Journal of the Royal Asiatic Society*, speaks of the Roman coins which circulated in southern India freely, and Roman bronze small change, partly imported and partly minted at Madura, was commonly used in the bazaars. So much connection grew up with Rome and the south of India, that "considerable colonies of Roman subjects engaged in trade were settled in southern India during the first two centuries; while the beautiful large ships of the Yarns' lay off Mousiris, to receive the cargoes of pepper paid for by Roman gold."

The Tamil poems speak of the importation of Yavana wines, lamps and vases into Southern India; and their testimony is confirmed by the discovery in the Nilgiri megalithic tombs of numerous bronze vessels similar to those known to have been produced in Europe during the early centuries of the Christian Era. And again:—"The Tamil States maintained powerful navies and were visited freely by ships, from both East and West, which brought merchants of various races, eager to buy the pearls, pepper, beryls and other choice commodities of India, and to pay for them with the gold, silver, and art ware of Europe."

Looking-glasses formed an important item in the goods for presentation to the Moghul Emperors by the foreign merchants. For an account of Justinian's efforts to introduce silkworms into the West, and the general commercial connection of Rome with India, see Gibbon's "Decline and Fall of the Roman Empire," chapter xli.

THE HOUSING QUESTION IN BOMBAY.

In the course of his speech introducing the Indian Budget in the House of Commons on July 26th, Mr. Montagu, the Under-Secretary of State for India, made some interesting remarks on the housing question in Bombay, in the course of which he quoted from the paper on this subject read before the Indian Section of the Society last year by Mr. G. Owen W. Dunn. "Technical instruction," said Mr. Montagu, "in special trades and occupations is impossible in sparsely populated districts. But, on the other hand, there is danger that all the evils of town life—the overcrowding,

the destitution, and all the squalid misery of mean streets with which we are too familiar—may be reproduced in India, and be even harder to bear than here on account of the suffocating heat. Already we hear of overcrowding and insanitary tenements in the operatives' quarters in Bombay. Mr. Dunn, late Chairman of the Bombay City Improvement Trust, in a paper of February 17th, 1910, says :—

"'The rooms or "chals," less than ten feet square, are separated from one another by partitions of wood or split bamboos, plastered with mud. There is no ceiling, only the sloping low roof, which is of rough round rafters, and a single thickness of country tiles. The walls and roof are black with smoke and dirt of many years; the rooms are filled with choking smoke from the wood fires and naked lamps, and there is no exit for this except through the rough doors. The only openings are the doors leading from the rooms on to narrow verandahs, no ventilation, darkness, and a choking atmosphere, and a family of five or six persons, with perhaps a lodger or two. Refuse of all kinds is disposed of by the simple expedient of throwing it outside beyond the verandah, and the condition of the surroundings of the "chal" may be left to the imagination.'

"In Bombay a city improvement trust has been working for the last ten years with inadequate means. The Government of India have now given, as I have said, £333,000 to it, and proposals are being considered for providing the trust with a larger income from local sources. A similar trust is now about to be created in Calcutta. In Rangoon, again, land reclamation on a large scale is being undertaken. Elsewhere much attention is being paid to the subject but the most urgent need is the education of the masses in the principles of hygiene. There is a limitless field, indeed, for private enterprise here. Tolerable though archaic habits and practices may be in the open country, when transferred to the crowded town they become unsupportable. If there were less ignorance and less perversity, plague would never find in the country the lodgment that it has. It is an established fact that persons living under proper sanitary conditions are virtually exempt from the disease. Plague does not attack the gaol population or the native army; it attacks the ordinary civil population, because they live in houses which are not rat proof, because they treat the rat almost as a domestic animal, because large numbers of them refuse to trap or kill it, and because they will not adopt the sanitary precautions which are pressed upon them."

ARTS AND CRAFTS.

The Board of Education Circular.—From the circular of the Board of Education on the subject of art education generally, and more particularly of the national competition and other examinations (of which extracts were printed in the *Journal* of July 21st), it is apparent that the Board has in view some very radical measures of reform.

In the first place inspection is in the future to take the place of the more elementary examinations. And on this subject it may be as well to say a few words. Some of the teachers are under the impression that the proposal is to abolish examinations altogether and substitute inspection for them, whereas what the circular explicitly proposes to do, for the moment at any rate, is to put an end to "the elementary examinations now conducted by" the Board "as well as the minute subdivision of art studies for examination purposes, and to substitute examinations of a more comprehensive character adapted to the needs of students who have reached a fairly advanced level in their studies."

In the second place, the existing tests for Art Class Teachers' and Art Masters' certificates will be brought to an end in 1912 and new regulations will be issued.

Thirdly, some experienced head masters of schools of art and others are to be invited to consult with the Board as to the lines upon which a reformed National Competition can best be established.

Finally, with a view to considering how the new policy and the reforms generally can best be carried out, it is proposed to establish a standing Committee of Advice for Education in Art for a term of three years from September 1st, 1911.

The Board's proposals are naturally rather tentative at present, but they are all in the right direction. For years past thousands of students have sat for examinations so elementary in character that the judging of the work by artists of standing has really been sheer waste of time; and if the stoppage of these elementary tests creates a few difficulties, there is no reason why in a year or two's time they should not all be overcome. The present method of examination for teachers' certificates has for years been considered unsatisfactory by teachers of the most different schools of thought, and everyone will welcome a change in the regulations in regard to them. It is satisfactory to note that the new scheme proposes to make some provision for testing the teaching powers of candidates. Is it too much to hope that the necessity at the present time of providing equally well trained teachers for all types of schools—schools of art, secondary schools and some of the larger primary schools—will be recognised? As to National Competition, it has served its purpose well, and it would be a great mistake to abolish it without putting something else in its place, or to give up the annual exhibition of the best work of the best students, but there has been for some time past too much show work executed especially for the competition; and the rapid growth of craft exhibits in recent years, and the absence of a set plan of making awards for craftsmanship or design, has made the judging some-

what confusing both for examiners and students. It has sometimes been difficult to know whether design, or craftsmanship, or both, or only some undefined sort of "charm" was the determining factor for which the prize could be said to be given. Many teachers are saying that the Board's proposals are very vague, and some are complaining of certain parts of the scheme; but there appears to be a very widespread feeling that the proposed changes are for the most part quite on the right lines.

When we turn to the composition of the Standing Committee the position seems to be, from the point of view of Arts and Crafts, a good deal less satisfactory. Its members include two or three officials, three prominent head masters, four painters, and a few business men (some of them connected with manufactures into which art enters largely, and one a member of a prominent shipping firm). But there is only one architect on the list, and Professor Selwyn Image, whose exquisite taste no one could doubt, but who would be the last person to consider himself an expert trade designer, is the only man who can be said in any way to represent design. It is true that the Director of the Victoria and Albert Museum has a seat, but when one thinks for a moment of Sir Cecil Smith as the former Keeper of the Greek and Roman Antiquities at the British Museum, one realises that, whatever his qualifications in other directions may be, he is hardly likely to be well versed in industrial design. The circular states that the chief examiners in painting and modelling, and the visitor for sculpture and modelling, who are not yet appointed, will be added to the committee—but it does not so much as hint at the possibility of the appointment of a designer. There will thus be five painters (without counting Sir Charles Holroyd, who sits as Director of the National Gallery) and two modellers on the committee, and only one architect and one designer. No one doubts the importance of painting; but for the purpose in hand, and in view of the work before the committee, and the growing importance of trade and technical schools, the number of painters, as compared with other kinds of artists, seems altogether out of proportion.

Works by L.C.C. Scholarship and Exhibition Holders.—A selection of the works entered in competition for the various art and artisan scholarships and exhibitions, offered by the London County Council, was on view for a couple of days this month at the Central School of Arts and Crafts, and was, as this little exhibition always is, very well worth a visit. The show was carefully arranged, and the exhibits as a whole were quite interesting, but it does seem a pity that the authorities do not see their way to giving a little information as to the various schools from which the different works come. It is easy to see that, just at this particular stage in his career, it might not be the best thing for the student gaining, say, an artisan scholarship, that his name should be brought too prominently before the public, but there seems no adequate reason for withholding the name of the school in which he has been trained—and to the majority of those who visit the exhibition its value would be materially increased if they could not merely see what is being done in London, but could learn at which schools the best teaching of various classes is being given. It is true that the officials in charge are courteously ready to answer questions, but they do not themselves appear to know always from which schools the exhibits come, and the ordinary visitor has some hesitation in asking an unlimited number of questions.

This year's exhibits show very plainly how quickly fashions change. Jewellery, which some years back was one of the best represented subjects, is this year responsible for so few examples that it can hardly be seriously said to count; and cabinet-work, which a short time ago occupied a considerable amount of space, is much less in evidence than in former years, though there is a little collection of carving, and some of the pieces are very well and cleanly cut. Book illustration, again, is by no means so conspicuous as it has been in past years, and the few designs for bindings, casings and wrappers are anything but satisfactory. Typography has been coming to the fore of late, and some of the work shown this year is extremely well set out and spaced with a good deal of care and taste. The tooled book covers, on the other hand, though generally good in workmanship, seldom show much appreciation of the best way to treat the space at the student's disposal, or a very clear understanding of the value to be got, even in the most elaborate work, by leaving a certain amount of plain ground. There is some quite excellent lettering both for painting and carving, though the one advertisement shown is lacking in attractive power. The script, too, was some of it very good, but the little ornaments filling up the ends of the lines were often quite futile. There was a fair show of museum studies and some drawings from nature, and one very good repeating pattern; but taken as a whole the designs for manufacture formed a very poor show, and the habit of sending them up for examination with no indication of the repeat, though it may make them look rather tidier, does not show a very workmanlike understanding of the best way of presenting an allover repeating pattern. The larger metalwork, of which a very fair amount was on view, is eminently serious in character, and is generally good both in technique and in form. Of embroidery there was a very large exhibit; some of the work was very well executed and a little of it (which looked as though it all came from one school) showed a remarkably good and fearless sense of colour. On the whole, however, there was a good deal of sameness in design and treatment about the work, and anything like boldness in design was conspicuous by its absence. This same want of boldness characterised the workmanship also. Much of the stitchery is really very fine, but it does not seem to have occurred to the students that in artistic

needlework it is at least as important to preserve the lines of the drawing and the sweetness of the curves as to take small stitches.

There are no very remarkable features differentiating this year's exhibition from those which have gone before, but the general level of technical accomplishment seems to be rather higher than it used to be.

EMPIRE NOTES.

An Imperial Council of Commerce.—A very important proposal emanating from the Congress of Chambers of Commerce of the Empire, held in Sydney, New South Wales, last year, has found expression in a meeting held last month, at the instance of the London Chamber of Commerce, on the subject of forming an Imperial Chamber or Council of Commerce, with headquarters in London. The proposal had been endorsed by the Associated Chambers of Commerce, at their meetings in London in March last, and carried with it, therefore, the active approval of all the Chambers represented by that Association. The objects of the new Council are stated to be:—To increase the inter-Imperial trade interests of the Empire; to collect and distribute Imperial commercial intelligence amongst different chambers; to focus and distribute reliable information as to each country's needs and powers; and to act as an Imperial clearing house for commercial information and suggestions. The chairman of the meeting stated that the London Chamber of Commerce was prepared, for the first three years at any rate, to provide officers and staff, and to raise the necessary funds. Resolutions approving the formation of the Council and confirming the existing Congress Organizing Committee, with its officers, under the title of the British Imperial Council of Commerce were adopted, and the opinion was expressed that the establishment of such a Council was a movement of world-wide importance. This opinion will certainly be endorsed, and that most cordially, by the members of a society like this, one of whose chief objects is "the Encouragement of Commerce," and not only of commerce as it affects the home manufacturer, merchant, and trader, but as it affects all the business men of our Empire beyond the seas.

An Ontario Rolling-Stock Enterprise.—A company has just been formed in Ontario for the manufacture of rolling-stock for railways and tramways, with a capital of a million dollars (£205,479). There is said to be a good field for a concern of this kind in Canada, where transport facilities are being rapidly extended in all directions. Many new tramway services, also, are likely to be established in the Dominion during the next few years. Regina (Alta) is having the cars for the tramway service, about to be started there, built in England, which, it is alleged, would have been made in Canada if works of the kind now projected had been established. Other industrial developments are being promoted in Ontario; one of them is the erection of a large flour mill on the Lachine Canal, the capital of which is also to be a million dollars. The creation of these new industries is a further indication of the intention of our Canadian fellow-subjects to make their country independent of the manufacturers of the Motherland, and emphasises the necessity, to which attention has frequently been called in this column, of home capitalists and leading manufacturers giving heed to the openings for their capital and enterprise in our oversea Dominions.

Siberian Alfalfa in Saskatchewan.—One of the problems which the Canadian farmer of the North-West has to solve is the provision of winter fodder for his cattle, as there are no indigenous grasses which can be cultivated in the northern provinces suitable for the purpose. The Saskatoon Board of Trade, therefore, has just secured several hundred one-year-old plants of the Siberian alfalfa, as, in the opinion of Professor N. E. Hansen, of the United States Agricultural Department, the alfalfa may be grown right up to the Arctic circle. Professor Hansen was sent by his Government on a tour of investigation in Siberia, and has recently returned, bringing with him a large number of alfalfa plants, some of which, as stated above, the Saskatoon Board of Trade has acquired. If, as it is hoped, this valuable grass will grow in the north-west of Canada, land which is now practically useless may be made worth £20 an acre.

Western Australian Caves: a New Discovery.—The limestone caves of Western Australia, discovered on the south-west coast some years ago, have proved a great attraction to that part of the country, and are regarded as second only in beauty to the Jenolan caves of New South Wales. But, according to the report of a further discovery recently made, the Jenolan Caves may take a second place. Referring to the Moondine Cave, found near Karridale, a few miles from the south-west coast, the Colonial Secretary says: "I have seen all the other caves in Western Australia, and also the well-known Jenolan Caves of New South Wales, but I say without hesitation that the Moondine, which is to be known in future as the Coronation Cave, far excels the whole of them. After four hours' exploration, two large beautiful chambers, which it is proposed to call King George and Queen Mary respectively, were discovered. Each of them is far superior in beauty to any cavern in Australia. I am certain from the conformation of the country that the cave will be found to contain still more beautiful chambers."

Australian Irrigation Areas.—Dr. Elwood Mead, who last year visited this country in the interests of the Victoria irrigation schemes, and for the purpose of securing settlers, has just issued a report on the northern Murrumbidgee district, New South Wales, in which he says that when the plans are completed for irrigating the 350,000 out of the 1,344,000 acres comprising that

district, 200,000 people will be able to live in comfort, where at present there are only a few landowners and stockmen. To make this land ready for settlement will require the building of about 2,000 miles of canals and ditches. An equal mileage of roads will be needed, and about 10,000 farmhouses must be erected by the settlers, or by the Government on their behalf. Dr. Mead strongly recommends the building of these houses, the fencing of the land, and the clearing and ploughing of a few acres of the various holdings, as nothing, he thinks, can be more attractive to the intending settler than to know he has a small ready-made farm to which to go. The money necessary for this purpose will be provided by the Government, who are prepared to extend the time of repayment so as to meet the requirements of men with small capital.

New Zealand's Homes for Workers.—To meet the needs of the working population of the Dominion, the Government are about to start their Workers' Home Scheme. The architect of the Labour Department has therefore prepared eighteen designs, representing houses ranging in cost from £120 for two rooms, up to £620 for eight rooms. Four or five-room cottages have been designed, costing from £255 to £325. Copies of the plans and descriptions of these houses have been sent to all the principal post offices, where they may be inspected by applicants, and, in the event of any particular design being selected, the applicant is supplied with the necessary plan and specification free. The maximum amount which the department is prepared to advance, in any one case, is £450. In view of the house-planning schemes which are now so numerous and so popular in this country, it is interesting to mark the progress which is being made in this direction, in his Majesty's Dominions overseas. It is to be hoped, however, that in the Colonies, as well as at home, the designs selected may have some artistic merit, and that everything may not be sacrificed to cheapness.

The Timber Resources of Papua.—Reference has on several occasions been made in these columns to the great natural resources of Papua, of which timber is so important a part. Samples of six selected Papuan woods were sent some months ago to be tested at the Melbourne University Engineering School. A report of their tests has just been issued, in which it is stated that the Uloba is found to be a strong and durable wood, capable of resisting the termite (the white ant) but not the teredo navalis (the well-known sea worm). In this respect it differs from some of the Australian eucalypts, which can resist the teredo but not the white ant, though it resembles other eucalypts which can resist the white ant but not the teredo. The eucalyptus marginata (Jarrah) of Western Australia, however, in certain conditions, can resist both. Uloba is said to have excellent bending strength, and will therefore be specially useful for building purposes. The Kokoilo, which is a light and cedar-like wood, is not durable in damp positions, but may be useful for panels, as a substitute for cedar. Its bending strength is also good. The Alaga is a fairly durable, close-grained wood, with fair bending strength. The Tamanau is described as moderately durable, medium-grained, and light pink in colour, but with poor bending strength. The Madave is coarse-grained, with moderate bending strength, and is not durable in damp positions. The sixth sample tested, the Ilimo, is soft and rather open-grained. Laboratory tests of this character have their value, but for commercial purposes the best test is the practical one of actual use. Until, therefore, the Papuan timbers have been tried in this way, it will be impossible to say what market value they are likely to possess.

The Rand's Record Gold Output.—The output of gold from the Rand in May is the largest on record for that great and prosperous field. The highest previously attained was in March last, when the returns showed 676,065 ozs. valued at £2,742,390. May's returns give 685,951 ozs. at a value of £2,913,734. Of this large yield, the share of the Witwatersrand was 658,196 ozs., valued at £2,795,839, while the outside districts showed a return of 27,755 ozs., valued at £117,895. The total number of stamps employed in the batteries is 9,978, and the tube mills number 218.

Indian Railway Traffic and Trade.—The reports of the fourteen Indian railways, just issued, show an average increase in the earnings of all the railways but two, and the falling off in the returns of the latter appears to be due to local and exceptional circumstances. Two indications, in all the returns, point to a very promising and continuous expansion of trade: the first is, the increase of passenger business, at a time not considered favourable for pilgrimages and other religious duties, which proves that better conditions obtain among the agricultural population, owing to good monsoons; and the other is the fact that freight business has not expanded so generally, on account of a decrease in the movement of food stuffs to districts where a shortage previously prevailed, which is due to the local crops turning out so well that there was no need for the bringing in of grain from the outside. These are certainly very satisfactory indications, in which all who are interested in the progress of our great Dependency will rejoice.

CORRESPONDENCE.

FIRE INSURANCE IN VANCOUVER.

The business section of the city of Vancouver has become so valuable that high buildings are a necessity. They must be sufficiently fireproof to meet the requirements of underwriters in order

that they may be rated at minimum premiums. The business of fire insurance is largely in the hands of American companies; what British and Canadian companies there are have combined with the American companies in adopting uniform rates of premiums.

Materials used and methods of construction in buildings within the municipal limits have to be approved by the Mainland Fire Underwriters' Association, an American institution working in conjunction with the Chicago Fire Test Laboratory. Only such materials or appliances as have been submitted and tested by the Chicago Laboratory and have obtained its label or certificate will be recognised. Should, therefore, any British manufacturers of steel casement sashes, rolling or sliding fireproof doors or shutters, etc., wish to supply their goods, they must submit to the expense of sending their goods to Chicago and pay the fees (which are very high) for inspection, before any business can be done. For American makers this is comparatively easy, but for British manufacturers exceedingly difficult and costly.

I can take the line of least resistance and purchase goods from the States that have the Association's approval, but being still a Briton, and agent for British firms, I naturally prefer to further the interests of my own countrymen, and it does seem anomalous that a part of the British Empire should be dominated by a foreign, though neighbouring, country.

I should be glad to know that some steps can be taken to remedy this injustice.

W. C. THOMSON.

Vancouver, B.C., July 17th, 1911.

GENERAL NOTES.

THE LEATHER DEPARTMENT AT LEEDS.—According to the annual report of the Department of Leather Industries in the University of Leeds, it appears that during the year 1910-11 there were nineteen students in the day classes and twenty-five in the evening classes. A considerable amount of research work is being conducted, and some valuable papers have been published. Three students have taken degrees in Chemistry and the Chemistry of Leather Manufacture, and some changes in the curriculum have been sanctioned by the Senate with a view to meeting the requirements of Honours B.Sc. and M.Sc. students. A former student of the Department has been appointed Leather Trade Expert to the Madras Government, and other industrial appointments have been obtained.

THE TEXTILE INSTITUTE.—The congress of the Institute for this year will be held in Belfast from September 7th-9th. A number of papers will be read, and visits paid to industrial centres.

THE MUSTARD BEETLE.—The Board of Agriculture and Fisheries have received information that the mustard beetle (*Phaedon betulae*) is doing much damage in some districts this season. They desire therefore to direct attention to measures which may be adopted to combat this pest. The beetles hibernate in various shelter places—*e.g.*, in the mustard stubble, in the hollow stems of other plants, in the neighbourhood of the food plants, and in crevices of many kinds. Eggs are laid in spring and summer, and both grubs and beetles feed on the growing plants. Pupation of the grubs takes place in the soil. The beetles may be attacked—(*a*) by dislodging and trapping them by dragging tarred sacking over the young plants when the beetles are observed upon them, and (*b*) by spraying the infested crop with arsenate of lead, which may be obtained ready for use in the paste form, and may be employed at the rate of 4 lbs. of the paste to 100 gallons of water. It has been observed that later in the year the beetles at times migrate in great numbers to other fields, and when this takes place a shallow trench should be dug across the path of the migrating swarm. If the trench is kept tarred many beetles will be caught, notwithstanding the fact that they have wings. After infestation the stubble may be burnt over before ploughing in order to destroy hibernating beetles.

THE INSTITUTION OF MINING AND METALLURGY.—The Council have, on behalf of the Institution, accepted an invitation from the Canadian Mining Institute to hold a joint meeting in Ottawa or Montreal about the first week in March, 1912. It is proposed to arrange a visit to one or two important mining camps after the meeting.

THE MUSEUMS ASSOCIATION.—Count Plunkett, F.S.A., the Director of the National Museum of Science and Art, Dublin, has been unanimously elected President of the Museums Association. The next annual conference of the Association will be held in Dublin, in July, 1912.

THE AUSTRIAN MINERAL-WATER INDUSTRY.—The home product of Austrian mineral springs is divided among the states of the Empire as follows, the figures representing bottles: Bohemia, 27 millions; Styria, 5 millions; Carinthia, 2 millions; Moravia, 1 million; Tyrol, 100,000; Galicia, 66,000; Upper Austria, 31,000; Dalmatia, 20,000; Lower Austria, 15,000; Bukowina, 15,000. The output in bottles of Bohemia's mineral springs is approximately as follows: Giesshübel-Sauerbrunn, 11 millions; Bilin, over 4 millions; Krondorf, over 4 millions; Carlsbad, 3 millions; Teplitz-Schönau, nearly 2 millions; Klösterle, 750,000; Marienbad, 600,000; Neudorf, 430,000; Franzensbad, 294,000; other mineral springs, 209,000. The bulk of the exports of Austrian mineral waters is distributed to Germany, United States, Italy, France, United Kingdom, Russia, and Roumania, the names of the countries being given in the order of their importance as importers.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

ETCHING.

By Frederick Wedmore.

Lecture I.—Delivered January 23rd, 1911.

The Old Masters.

Syllabus.—The Cradle of great Etching—Rembrandt's place—Ostade and Bega—Vandyke—Landscape and Animal Subjects in the Low Countries—The Classic Landscape—Claude—Links with the Moderns—Etching no "Minor Art."

From a printed notice which your Royal Society of Arts periodically issues, I gathered, with momentary forebodings, that your lectures here are expected very often to deal with technical processes. But had that wish been in the present instance your guiding motive you would have invited an etcher, and not a writer, to give the lectures I am now beginning. What etching is, as a craft, is to-day widely understood. No longer, even by the least equipped, is a scratchy little drawing in pen and ink spoken of as an etching. And, for myself, I take leave in this, as in every other Art, to be interested, and to ask the public to be interested, less in the serviceable processes of the craft than in the power of the Art to express with directness such different individualities, such different visions of the world. When the great etcher has gone through his performance—has completed his work—he has given us, not his work alone, but much of his soul. "*Qu'est ce que mon œuvre ?*" asks Maurice Barrès—a master in our craft of writing—and the answer that he gives is this, "*Ma personne toute vive emprisonnée.*"

You will note, from my little synopsis circulated amongst you, that I speak in these lectures almost entirely of two centuries—the seventeenth and the nineteenth. Of all the past, those are the great centuries for the art of the etcher. Your twentieth century is yet so young that it has scarcely shown its general character. In it, nevertheless, have been developed the talents of Cameron, Brangwyn, Muirhead Bone. Next Monday I speak of the etchings that may be called modern. To-day, of the seventeenth century; that is, to put it roughly, of the great Old Masters.

The cradle of fine etching was, of course, the Low Countries. In the seventeenth century, etchers who were great and were not of the Low Countries, were isolated men. Nay, but was there in that century more than one man who was great and neither Dutch nor Fleming? Was there anyone but the author of "Le Bouvier"? Really, outside Holland, with its Rembrandt the immortal, was there anyone but Claude?

First then, for us, the dominating Dutchman, and the inevitable and yet long-settled question, "What was Rembrandt's place?" It was the place of the inspired path-breaker. In the new vista that he opened for those who went upon his road, Rembrandt reminds one of the great initiators in music—takes his place beside them—Bach, it may be, or Berlioz. Rembrandt was an "Old Master"; but some of his work is of such a character that one says to one's self in looking at it, "Yes, but he was also the greatest of the Moderns." "Is it not true that the 'Landscape with the Ruined Tower'—that, more, I think, than any of the others—is the beginning of Modern Art?" The truth is, Rembrandt was a couple of hundred years in advance of his time. In him are the germs of the impressionism of Constable, and of the great French landscapists whom Constable influenced. His progress, technically, followed the course common to nearly every big man's progress—that is, it was a course from precision to breadth; from punctiliousness to that easy mastery that can be economical with learning. That is the course generally. But the *technique* of Rembrandt shows early and surprising advances,

and then, for purposes of the artist's own, a deliberate return, it may be, to the old method. So many themes "indicate"—in the medical phrase—the adoption of so many processes, from the days of Rembrandt's controlled and ordered youth, with his exquisite vision of that *grande dame* among the peasantry—his mother, in his "Head of a Woman lightly etched"—down almost to the days of that so flexible and yielding nudity, "The Woman with the Arrow," with which, substantially, he finished his life-work on the copper.

Another word, it may be, about Rembrandt later; but now I must ask you to transfer your thoughts to two important and unequally known masters of his day and land. One of them is Ostade, and the other Bega; and if I insist a little more upon Bega than upon Ostade it is because Bega has been, upon the whole, so much less considered. Let me make clear, however, that with that high appreciation of Ostade, which is now an accepted tradition, no fault is to be found. Ostade had nearly every quality, except a great soul. Had Bega a great soul? Perhaps not. He had a greater manner than Ostade, in any case. And, likewise, he had less variety. Both men arranged admirably their different materials. Ostade's "The Family" is an unsurpassed masterpiece of composition. Ostade's means of expression, as an etcher, were of extreme complexity--they were of serviceable changefulness.

And now Bega. You are sooner at the end of his resources of method; yet, within their boundaries, how noble his resources are! They are nobler than his themes—but that indeed is the truth about every Dutchman except Rembrandt. Bega's scenes are tavern scenes for the most part. His people pass from gross love to drinking, and from drinking to gross love. But, even in their excesses, how human; their characters how marked! their cordialities how unconcealed! The backgrounds of his pieces, simple, but with what broad and rich effects, what opulence of shadow and light! To possess a sample or so, at the least, of Bega's most individual excellence, becomes for the collector an obligation and a joy.

The art of etching, which could express the assured talent, and the decisiveness of stroke of Bega, could express, happily at the same time, no small measure of the grace of Vandyke, and all of his strength. His grace, moreover, is shown in etching quite independently of that which often prompted it in painting — the elegance, I mean, of courtly womankind. His etchings are a picture gallery of men. Most of them were his brother artists. There is "Vosterman's" for grace; "Vranx" for direct observation; there is the genial "Snellinx"—an etching which Philip Hamerton, rightly enough indeed, called "luminous and lively" — there is, above all perhaps, the portrait of "De Wael." I know you do not put these things—magnificent and authoritative though they are—quite beside the subtle "Clément de Jonghe" and the benign "John Lutma" of Rembrandt; but that is because Vandyke was the Walter Scott, while Rembrandt was the Balzac, of portraiture.

And keeping still Rembrandt as our standard of mastery, we shall not find that the landscape, or the landscape with cattle, of the landscape men of the Low Countries, even of Adrian van de Velde, can be looked upon as altogether on a plane with the landscapes of Rembrandt, at once subtle and overpowering—with that "Landscape with the ruined Tower" I have spoken of already, or the "Landscape with the Obelisk," or the "Cottage and Dutch Hay Barn." No doubt the classic landscape, the more or less classic landscape, of Both, Berghem, and Waterloo, have a course and a charm of their own, making comparison inappropriate. And—but we should first give a word of recognition to the Master of Prague, Wenceslaus Hollar, who worked in England, patronised by the Earl of Arundel, and died here after a life of production laborious and ill-paid—it is the classics that best lead us on to the consideration of Claude. The classics—Both, Berghem, Waterloo—have style, that indescribable quality; they have style, all of them But in style Claude stands above them, because Claude is the very standard of style. It is Claude who sets the pace.

It is unfortunate that of Claude's two dozen or so etchings, very few are apt to be seen by the public in the condition which is necessary, if their pre-eminence is to be appreciated. Etching did not fill a large place in Claude's life. His practice of it was intermittent. Sometimes it was perfect, and sometimes technically imperfect. And, after comparatively few impressions, care was not taken of the coppers. And Claude worked much in isolation, as far as etching was concerned. In his own day his prints were appreciated by but the smallest public. Rarely, I think, can they have had a market. It is to these various causes I assign the present scarcity of the fine ones. Nothing, then, should prevent the collector from laying his hands, where he can, upon those subjects and

upon those impressions which veritably represent this master. The two or three dance subjects—happy peasants in untroubled weather, by quiet waters or under graceful leafage—these things are desirable. So is "The Wooden Bridge." And even more so, in an impression that truly represents the plate, is "The Cattle going Home in Stormy Weather." "In *Showery* Weather," would perhaps better define it. Then there is the popular and famous "Sunset"—No. 15 in Robert Dumesnil's catalogue. And then, above all, I must suppose, towers of right, "Le Bouvier"—a glade, a stream, and the cowherd bringing down the dark cattle. Yes, confessedly, "Le Bouvier"—in a fine impression of it—is the master's unequalled masterpiece.

So much for the seventeenth century. I have said before that little was done in the eighteenth. In England and in Holland, nothing. The slow approach to the true Moderns is to be found, if found at all, in Italy and France; dare I localise it more closely and say, "in Rome, in Venice, in Provence"? Piranesi was at once the recorder of actual Rome, and, in his prison scenes, a dreamer of weird dreams. Tiepolo etched with impulse; sometimes almost with majesty. Canaletto etched with more of continuity and more of calm; never with undue emphasis. I remember Monsieur Béjot pointing out to me that, unlike some more fashionable contemporaries of his own—but Béjot did not put it in that way—Canaletto never made excessive use of black. He did not exaggerate his shadows: no superabundance of mere printer's ink was invited to furnish him with mystery and weirdness, "while you wait."

In France, though people do not know it, the connecting link with modern times was Honoré Fragonard, author of but a few plates, and these neglected even to-day. Child of Provence—where France from remote ages, has most, in aqueduct and tower, in road, in bath, and in arena, betrayed—preserved rather—the closeness of her association, with Rome, and the measure of her debt—what wonder that Fragonard, in his spontaneous fancies on the copper, is himself joyously classic! Nymph and faun occupy his little plates and enliven them. The few pieces have little commercial value; but, I assure you, they are charming.

Back let us go, however, for a moment, just to end—and for a purpose—with those two consecrated names, Rembrandt and Claude, the greatest etcher the world has ever seen, and one of the greatest. These, each in his kind, were men of noble souls, and boundless, tolerant vision; and the art in which they expressed themselves with unsurpassable charm is called, even to-day, by some—rather grotesquely if we think—a "minor art," like enamelling, or lace-making. By minds bound down by convention or limited by thoughtlessness, or want of imaginative grasp, a work of art is apt to be judged by size, by visible ambition, by supposed quality of material. And yet "the coin outlasts Tiberius." Let us receive this lesson, that as men's entrance into the understanding of Art becomes the surer, the less are they inclined to consider one medium as in itself greater, more dignified, than another. More and more are they inclined to value, and to applaud, most of all, the choice of the right medium for the particular theme and the particular temperament. That choice was made, and wisely made, by all the great etchers.

Lecture II.—Delivered January 30th, 1911.

Modern Etching.

Syllabus. — Goya — Wilkie and Geddes — The Silence before the Revival—The great French Outburst—Méryon, Bracquemond and Jacquemart—Haden and Whistler—Themes mainly Landscape, Portraiture, Architecture—The Etching of To-day.

Every young painter who puts forth a claim to be considered, in work and in opinions, up-to-date, feels, just at present, the necessity to be enthusiastic about Goya. Goya was not only gifted—that would not have sufficed at all. Goya was audacious; he was revolutionary. A modified Benvenuto, set in the key of the late eighteenth century, this masterful erratic Spaniard disturbed many comfortable conventions in life as well as in Art. All question of contemporary fashions apart, however—and putting quite into the background the fascination of the man for modern men and women—it seems to me unlikely that Goya's fame, either as a painter or as etcher, should grow less, so fertile was his mind in ideas, so quickly roused his indignation, so prompt and telling his satire, so weird and changeful his fancy, and so certain his hand. Effective in the "Disasters of War," and in the Bull Fight series, it is in the "Caprices" that his art is at its height. Their conceptions are amazing and infinite. Would that the plates, dexterous and brilliant blends of line-etching and aquatint, had been taken better care of, had been more *soignés*, from the first! Then they might have been put into the solander-boxes of the collector, with long accepted master-

pieces. Now, in book-form, each series is nursed for a while upon the knees, with not much more of reverence than the hero of "Fifine at the Fair" would have bestowed, he tells us, on "Doré's last picture book." For all that, Goya is great, and our young artists' and fashionable amateurs' appreciation not in the main erroneous.

In Goya's early days, our Crome—"old" Crome—was doing a few admirable etchings at Norwich—"Mousehold Heath" was the best of them—and in his later, Wilkie and Geddes, in London or in Scotland, were doing respectively "The Receipt" and "Peckham Rye." But, practically, very little of lasting value was done between the time of Rembrandt and the full middle of the nineteenth century, when, not to speak in detail of Bracquemond and Jacquemart—the great etcher of birds and the great etcher of porcelain and *objets d'art*—there burst upon the world—it was in the early fifties—the pregnant and magnetic genius of Méryon. Méryon, in virtue of the dozen or sixteen prints which constitute his more important work—his "Etchings on Paris" (the "on" be it noted, is his own)—is to-day accounted a classic, and, in the print market, hardly a Dürer, hardly a Rembrandt, fetches a higher price than does "L'Abside de Nôtre Dame." This "Abside" —an inspired record of the cathedral church as it is seen from a hundred yards or so east of it, from across the river—is perhaps of all great pieces, certainly of all Méryon's great pieces, the piece most "understanded of the multitude"; but it makes no concessions, it bends to no prejudice; it holds its lofty dignity. None the less, the real collector and the serious student, recognising the height of its beauty, crave to have placed beside it the "St. Etienne du Mont," the "Galérie," the "Morgue," even the "Stryge." Nor does the list stop here, for I said, not four or five, but a "dozen or sixteen." Each slow, deliberate plate of Méryon's, an etching as to its method and medium, an original "engraving" as to its spirit, is a thing not only of immense leisure of execution, but of permanence deserved and undeniable.

The absence of any imagination so exalted and noble as that which Méryon's prints reveal, is to be noticed, but is not to be wondered at, in the work of men who immediately succeeded him. His qualities were of necessity exceptional. If they were shared at all, they were shared by Legros, and then "with a difference." Seymour Haden's qualities, and Whistler's qualities, bear practically no likeness to them. In four years—from the year 1850 to the year 1854—Méryon wrote his "Epic of Paris." Illness—mental illness—had attacked this genius by the time that Haden and Whistler settled to substantial work. That was one or two years only before 1860. Legros—and with the weirdest of his themes—had been a little before them. His earlier art was concerned greatly with ecclesiastical life and legend and with definite portraiture; his later art has had as its theme, more particularly, landscape, good in itself, but which he has refined and ennobled; and I do not know whether to prize the most "Communion dans l'Église St. Médard" and "Les Chantres Espagnols," or, in the later art, "Le Mur du Presbytère," or "Le Pré ensoleillé."

It seems late in the day to speak to you in any detail of Whistler and Haden. Haden's place was the more promptly admitted, and the "Breaking-up of the Agamemnon"—always a *chef d'œuvre*—was an appropriate wedding-present when an etched Nocturne of Whistler's would have been held to be either an enigma to which there was no answer, or a joke of which the point was not discernible. As time went on, the piquancy of much of Whistler's work and his alertness, not to say his aggressiveness, made him noticeable; but he was in his grave before amongst the large public there was any intelligent understanding of his merit. Haden's work was not wanting in originality because it was conservative of tradition; and its conservatism of tradition did no doubt facilitate the promptitude of its appeal. His etchings retained, most of them, the unity of a sketch, but the sketches were classic. I remember he appreciated Whistler very much more than Whistler appreciated him. He told me once—that was many years ago—that were he to part with his Whistlers and his Rembrandts he did not know which of the two would go first.

Whistler's method changed more visibly and frequently than Haden's. We note in it more easily a succession of periods; the Thames period, the Leyland period, the Venetian period, the late Dutch period, to give examples of what I mean. In Haden's work all that we note in this respect is that which I have called before now the customary progress from precision to assured freedom, and in connection with the added breadth, a breadth more sought for, the employment not unfrequently of another metal than copper—the employment of zinc, that gives what is sometimes desirable, "a fat line."

Méryon, Legros, Bracquemond and Jacquemart, Haden and Whistler, prepared the way for the etchings of to-day, in England and France. And the etching of the last few years—the last twenty years—in England has, strange to say, accomplished much more than has been accomplished in France, where coloured etching (practised sometimes exquisitely enough, as by Monsieur T. F. Simon) seems to me on the whole so much less worthy than the etching which, apart from the question of line, concerns itself with gradations of black and of grey up to the white of the paper, and leaves actual colour severely alone. In France, as far as black and white are concerned, we have chiefly to recognise Lepère and Béjot. They are the two masters, and, of both, landscape, and the landscape of cities, is the theme. Béjot, in serene mood, illustrates charmingly the Paris that he loves. The themes of Lepère, in his etchings—not, of course, in his wonderful wood engravings—are country or provincial themes, often. The special character of Paris he seizes less readily than his younger contemporary, Béjot. But in pure sketching you have his "Béguinage, Bruges," and in work carried far, yet never too far, his group of pieces of which the scene is Amiens with its great dominating church.

America, since Whistler, has given us one etcher of high importance, Mr. Maclaughlan, who has his vision of Paris, too, and who has brought home to us all Switzerland, as it were—all the mountains and deep, wide valleys—in his "Lauterbrunnen." Sweden has given us Zorn, who, not to speak of his frequent pre-occupation with the moneyed American, has recorded in a *chef d'œuvre* Renan; in a *chef d'œuvre* Anatole France. Moreover he has seen and rendered the nude—the nude of every day—in a new way in etching. He will last.

But we end with the English—the English who include the Scotch. Strang—a Celt, I must believe—is himself imaginative, though visibly as a follower of Legros. Still, he is far from being only a copyist, an imitator, and he is an extremely capable craftsman. Frank Short, a veritable master of all the craft of engraving except line engraving, has his own vision of the stretched land and the extended waters and the encompassing sky. Haig, Hedley Fitton, Alfred East, Burridge, Goff, Watson, Sickert, Sparks, Luke Taylor, Watson, Mulready, Stone and Martin Hardie, Affleck with his "Toledo" like a "cry in the desert," and half-a-dozen others, were there but time, claim quite substantial comment. Roussel, of French birth but English residence, must certainly be named, in virtue of plates which, a thousand times less than some people suppose, repeat Whistler—they scarcely repeat him at all, but in the accident of their themes at Chelsea—and Roussel is the author of "A French Girl" and other dry points of the face and figure, of singular distinction, of high and lasting charm. Then, very notable, and now widely accepted, are Brangwyn, D. Y. Cameron, and Muirhead Bone. Bone is an instance of the truth of Dr. Johnson's saying, "much may be made of a Scotchman if you catch him young." Bone's dry points of London, the best of them, such as "Clare Market," "St. John's Wood," would make of him a little classic, but so would "Ayr Prison"; so, too, would "Leeds Warehouses." And sometimes scaffolding, in its complexities of line, suffices for him—scaffolding or the squalid suburb. Cameron asks generally for subjects more obviously noble, and, out of a masterpiece in one Art makes a masterpiece in another; he adds a glamour of his own to the "Saint Gervais," to the "St. Laumer," to "The Five Sisters of York." Brangwyn's plates are huge plates—too many of them, and according to Whistler "the huge plate" is an offence, but their hugeness does not destroy, although it may impair, their merit, or perhaps their fascination. Brangwyn's plates have their valuable individuality, their strength of draughtsmanship, their deliberate preoccupation with noble design. And to be preoccupied with noble design is, of very modern "notes," one of the healthiest and best.

CHINA AND OPIUM.

It would be difficult to point to any act of national renunciation quite like that of China in stamping out the use of opium. At the beginning of the present century the opium used annually in China equalled 22,588 tons, of which about one-seventh came from India. The Chinese Government has always been opposed to its use, but until it was able to regulate the import of foreign opium its efforts at suppression were perfunctory and ineffective. In 1909 the Powers interested met in conference, and resolved that it was the duty of the respective Governments to prevent the export of opium to any countries prohibiting its importation. Concurrently, the Chinese Government determined to compel the cessation of production and consumption of opium in China within a given number of years, and the British Government agreed to reduce the export of Indian opium by one-tenth of the amount annually taken by China, so that the export of Indian opium to China would cease in ten years. The result is given in the

remarkable despatches from Sir A. Hosie, which have just been issued (China No. 1, 1911). Sir Alexander Hosie has made personal journeys into some of the opium-growing districts, and has received reports from consuls and non-official persons resident in or acquainted with other districts; and, although he does not endorse some of the more glowing statements as to the complete suppression of poppy cultivation, and evidently commenced his inquiries in a sceptical spirit, his admissions are significant, whilst the statements of other competent witnesses are very remarkable. Take Shansi. "Not only," writes the Consul-General, "did the governor and provincial assembly assure me of absolute suppression, but all British subjects with whom I came in contact informed me that, to the best of their knowledge and belief, opium was no longer a product of Shansi, and the fact that his Excellency invited personal inspection of his province by a British official would appear to show that he was perfectly convinced that eradication was complete." Sir Alexander himself says: "There is reason to believe that the poppy has ceased to be cultivated in the province for the last two years." In Shansi, large opium establishments numbered fifty-six, with a capital of about 900,000 taels, while raw and prepared opium shops were scattered all over the province. These were all closed in the beginning of 1910, so that there is not now a single opium establishment or shop. Nor is this all. Not content with suppressing the cultivation of the poppy, the Government has sought to cure the opium-smoker of his craving. To quote Sir Alexander Hosie: "There are ten official refuges in different parts of the province through which over 100,000 smokers have passed and been cured, and this number is exclusive of persons treated in over 400 unofficial refuges. His Excellency estimates that from 50 to 60 per cent. of smokers in the province have been completely cured, and there still remain the old and the infirm, who are being advised to give up the habit, and will in the end be successfully dealt with."

When the Consul-General was in Hsi-ai-Fu he asked the Rev. A. G. Shorrock, of the English Baptist Society, who has spent many years in Shansi, and who was at the time of his visit collecting information regarding opium from all parts of the province, if he would send him a few notes on the subject, as soon as his information was complete. Mr. Shorrock did so. In these notes he writes: "The price of opium, as compared with former years, indicates, more than anything else, the rate of production now. More than four times the price is now charged, as compared with previous years." And Mr. Shorrock makes the following piquant observations: "Such a change is only possible when supported by popular sentiment. No other change appeals as this has done to the conscience of the people. I have seen the farmers take their implements to the mandarin and refuse to work when a comparatively small tax has been levied; but, although the people have incurred great loss by the suppression of opium growing, no such risings have yet taken place, at least to any extent."

Szechuan was for many years the greatest opium-producing province in China. The Consul-General estimated, when he was officially connected with the province in 1909, that the production exceeded 200,000 piculs, or about four times the annual importation of Indian opium into China. In 1908 the prohibition was imposed, with the result that in his despatch to Sir E. Grey of April 10th, 1911, Sir Alexander Hosie is able to write, "In not one of these districts did I observe the poppy, and the result of my investigations was fully corroborated by the testimony of missionaries whom I took the opportunity of questioning whenever possible. They had neither seen the poppy nor heard of its cultivation during the season of 1910–11. . . . I am satisfied that poppy cultivation has for the present been suppressed in Szechuan."

Yunnan has always ranked next to Szechuan as the second greatest opium-producing province in China, and the quality of its opium has always held the first place in the estimation of consumers of the native drug throughout the Empire. The total annual production of the province prior to the introduction of the measures for the suppression of cultivation and consumption taken in obedience to the Imperial decree of September 20th, 1906, has been variously estimated at from 30,000 to 78,000 piculs: probably 60,000 piculs would be a nearer approximation to the actual production. Sir Alexander writes: "Writing of this place—the greatest opium-producing centre in eastern Yunnan—which I visited in June, 1882, I said that judging from the number of withered poppy-stems to be seen among the summer crops of maize and beans, it must have been one field of poppy, and such it continued to be annually until the measures of suppression were introduced. From the time I entered Yunnan I heard that the poppy had not been cultivated for three years, and, as regards the Chao-t'ung plain, this was fully confirmed by the English Methodist Mission, one of whom has been resident in this and the neighbouring prefecture of Tung Ch'uan Fu for over twenty years. Not only had no opium been cultivated on the plain for three seasons, but, so far as they could ascertain, there was no cultivation of the poppy within the whole of the prefecture."

These despatches of Sir Alexander Hosie present a wonderful picture of the government of a great nation bent on the eradication of a national vice, and, aided by the willing acquiescence of the people, sweeping it from vast provinces.

THE TEXTILE FIBRE INDUSTRY OF BRAZIL.

With the world's source of cotton supply in the main limited to the United States, and in view of the reputed failures to develop the cotton-growing industry in India and Africa on a very large scale,

it would seem that Brazil will, within the next generation, witness an extension of its cotton industry, and when such a time comes its cotton-bearing trees will have their share of attention in this respect. There are indigenous to Brazil, and growing wild in certain regions, two well-known species of trees which are of interest to the commercial world because of their possibilities as producers of cotton fibre. Not the least remarkable feature about these trees is their occurrence in precisely those regions where it has seemed to be impossible, or at least difficult, to grow ordinary cotton. No other country in the world possesses so large an area of land which may be utilised for the growing of cotton as does Brazil, and that in other areas it is possible to cultivate trees for the production of cotton fibres must appeal to the textile-producing world as indicating that Brazil must be reckoned with as a future source of the world's cotton supply. The United States Consul at Rio de Janeiro says that one of these trees is called "Barraguda," from its being barrel-shaped, after the peculiar trunk which is its characteristic. The tree grows from twenty-five to thirty-five feet in height, tapering from the great bulge in the trunk to a very slender one, from which branches form about twelve feet above the ground. The trunk is entirely covered with hard and sharp thorns. The pods in which the cotton grows are from five to eight inches long, and two to four inches in diameter. The fibre is coarse and white, and adheres closely to the seeds, which are somewhat smaller than peas. It is a long and strong fibre, and while too coarse for use in textiles of any degree of fineness, it would, it is said, lend itself to the fabrication of blankets, cotton twine, and a variety of other materials. The habitat of this tree is in central and southern Bahia, and it grows to a lesser extent in the State of Pernambuco. The uplands on which it seems to flourish are from a thousand to sixteen hundred feet above sea-level, where there is a decided chill in the air during certain months of the year. The other tree produces a much finer cotton, of a brownish colour, exceedingly light, but not long enough to spin well, and resembles eider-down. The pods in which it grows are about ten inches long and one inch and a half in diameter before bursting. When the pod bursts and the ripe cotton comes out, the pod takes on a rotund shape eight to ten inches in diameter. The fibre adheres loosely to the seeds, most of which fall out by merely shaking the pod, and is so light and fluffy that one can blow almost the entire contents of a pod free from the outer enclosure or hull. Occasionally this cotton is used in pillows, and when properly prepared is said to be as soft and downy as the lightest and best feathers, showing no tendency to harden with use. The inner bark of this cotton tree is utilised by the inhabitants for many purposes. It is a remarkably strong fibre, and a strip half an inch in width will, without any preparation, sustain a weight of fifty to a hundred pounds. The tree has its habitat in central Bahia and northern Minas Geraes, being most abundant in the latter State, and is called "imbirussu," being a name of Indian origin, probably given to it because of its peculiar and characteristic bark. The corrugations of the bark form diamond-shaped patches, the inner parts of which have a bright, greenish-red and glossy surface. Both of these trees are hardy and long-lived, seventy-five to one hundred years being apparently a fair average for the period during which they bear cotton fibre, while the common cotton-plant bears in many parts of Brazil for fifteen to twenty-five years without any attention whatever.

ACCIDENTS IN MINES AND QUARRIES.

Part I. of the general report of the Chief Inspector of Mines, dealing with District Statistics of Mines and Quarries for 1910, has just been issued as a Blue Book [Cd. 5794]. The total number of persons employed in and about the mines of the United Kingdom was 1,078,083, of whom 1,049,407 worked at the 3,253 mines under the Coal Mines Act and 28,676 at the 663 mines under the Metalliferous Mines Act. In coal mines there was an increase of 35,409 persons over 1909. Of the total 848,381 were employed underground. Of 1,201,026 surface workers, 6,221 were females. The total number of workers under sixteen, surface and underground, was 72,094. At the quarries, 85,837 persons were employed. The output of coal in tons was 264,417,588, an increase over 1909 of 658,716. The output of minerals under the Metalliferous Mines Act was 3,241,453 tons, of which 1,851,351 was iron ore. Stone and mineral under the Quarries Act amounted to 46,138,751 tons, of which 4,987,613 were iron ore. The total iron ore produced from all sources was 15,226,015 tons.

With regard to accidents, there were at the mines under the Coal Mines Act 1,242 separate fatal accidents, causing 1,775 deaths. Compared with 1909, this is an increase of 60 accidents and 322 deaths. Of those killed, 114 were under sixteen, as against 95 in 1909. At mines under the Metalliferous Mines Act there were 38 fatal accidents and 43 deaths, the accidents being the same as the previous year and the deaths showing an increase of three. There were 80 fatal accidents in quarries, with 84 deaths, three fewer accidents than in 1909, but the same number of deaths.

Non-fatal accidents in coal mines causing disablement for more than seven days numbered 158,565, the persons injured numbering 159,042. At metalliferous mines, 1,578 accidents occurred, injuring 1,596 persons; at quarries, 5,156 accidents, injuring 5,175 persons. These figures show an increase over 1909 of persons injured—namely, 5,736 in coal mines, 162 in metalliferous mines, and 319 in quarries. The non-fatal accidents reported to inspectors were: In coal mines, 5,432 (a decrease of 43); in metalliferous mines, 281 (an increase of 18); in quarries, 1,385 (a decrease of 20).

In coal mines the death-rate was, of underground workers, 1·91 per 1,000 persons employed, as

against 1·61 in 1909; of surface workers, ·76 per 1,000, as against ·67 in the previous year; the death-rate of the whole was 1·69, as against 1·43 in 1909. Of persons under sixteen years, the death-rate was: Underground workers, 1·77; surface workers, 1·03; for both together, 1·58. Corresponding figures in 1909 were 1·49, ·62, and 1·26 respectively. In metalliferous mines the death-rate was 1·50 per 1,000 (1·41 in 1909)—underground workers, 2·16 (1·97 in 1909); surface workers, ·52 (·60 in 1909). In quarries the death-rate was ·98, as against 1·00 in 1909; for inside workers, 1·38 (the same as in 1909); and for outside workers, ·29 (as against ·36 in 1909).

The total number of deaths (1,775) from accidents in coal mines is the highest yet recorded in any one year; those from explosions have only been exceeded twice—in 1866 (651 deaths) and 1878 (586 deaths). The number of deaths from falls of ground is also the highest recorded, namely, 636. The report states that one must go back to 1890 to find a higher death-rate from all causes underground, namely, 2·09 per 1,000. That year, like the one under review, was marked by serious colliery explosions.

AN AEROPLANE POST.

The *Times* announces that an experiment in the direction of utilising aeroplanes in the postal service of the country is likely to be undertaken shortly by the General Post Office. The proposal is for a regular aerial service for a limited period between London and Windsor. Many details have still to be settled, and negotiations are now proceeding with a well-known airman for the supply of suitable machines.

The scheme is stated to owe its inception to the enterprise of a few gentlemen in London interested in aviation, their objects being to further the science of aviation in this country, to demonstrate the utility of the aeroplane, and to benefit certain charities. The last-named object was to be achieved by issuing special postcards and envelopes for the aerial service at 6*d*. and 1*s*. each respectively. All takings in excess of working expenses would then be divided among the selected institutions.

The Postmaster-General was approached on the subject, and not only gave his consent, but readily agreed to co-operate. The aerodomes at Hendon and Windsor Park were selected as the points to be connected by the service. Arrangements have been made with a number of large firms for the fixing in their establishments of special "aerial" letter-boxes, in which letters intended for the aerial service must be posted. Daily clearances will be made by postmen, and the collections will be despatched to the central clearing house. Here the letters will be placed in sealed bags and conveyed by motor-van to Hendon. At the aerodome they will pass from the direct control of the postal officials into the hands of the aeroplane staff. The bags will be securely fixed to the machines, and the airmen will then start on the journey to Windsor, covering the distance of twenty-one miles in, it is estimated, half an hour.

THE TRADE OF MARSEILLES.

The last Consular report on Marseilles contains some interesting information respecting the progress and trade of the port. The great public works in progress, or planned, the advance in technical education, the solution of sanitary and social problems, sound municipal finance, aided by a readjustment of local taxation, may soon be expected to bring about a noteworthy improvement in local conditions. The vast sanitary works, completed in 1897, since when public health has so greatly improved, soon to be followed by the purification of the Marseilles water-supply, now under discussion by the municipality after exhaustive tests, will have transformed the sanitary conditions of the town. The civil hospital is being rebuilt on modern lines, and the construction of a new hospital for contagious diseases is planned. Large public parks are being added to the existing ones for the recreation of the people and the health of its children. Sporting clubs, walking clubs, football clubs, amusement parks (started with British capital), are adding in a marked measure to the open-air life and the general improvement of the people. Wages earned are higher, but foodstuffs have, unfortunately, with the exception of bread, risen in price, and the two last severe springs have ruined the fruit crops, upon which the population so greatly depends. The spending power of Marseilles has increased, and there is a demand for a better class of articles and a greater variety as well. The brick and roofing and flooring tiles industry has taken a large development. Marseilles exports roofing tiles principally to Algeria, Turkey, Russia and Australia, and bricks mainly to Senegal, and flooring tiles principally to the Argentine Republic. Considerable capital is being invested in glass works, with satisfactory results. The paper works in the neighbourhood turn out about 900,000 tons of paper and cardboard per annum. The industrial activity of Marseilles has been shown in providing electricity and cheaper gas; in its mineral oil-refining works; the bauxite and aluminium industry; in sulphur-refining; in the production of soap, candles, glycerine, oils, tiles and chemicals; in sugar-refining and flour-milling; in the manufacture of macaroni and semolina; in its great trade with the colonies, importing their raw materials and exporting the manufactured products. The principal centres of industrial and agricultural activity of the district are the coal-mines of Grand Combe and Graissesac. Of the total quantity of coal of all descriptions (1,339,200 tons) imported by sea into Marseilles during 1910, 1,066,203 tons came from the

United Kingdom, the remainder from Germany (186,000 tons) and America (87,000 tons). The total importations of coal for 1910 show a slight decrease on the figures for 1909 (1,441,826 tons), the decrease being mainly attributable to the fact that many of the local factories which formerly used coal for raising steam-power now employ electric-power. The bauxite industry has made great strides during 1910. Total shipments from Marseilles amounted to 67,752 tons, as compared with 52,362 tons during 1909; shipments to the United Kingdom were 19,233 tons, as compared with 1,959 tons during 1909, a large increase. The shipments of bauxite show an increase of 50 per cent. at St. Raphael, in the Var, where 36,396 tons were shipped to Scotland and Germany during 1910; a slight decrease at Toulon, in the Var, 44,600 tons for 1910, and a decrease of 25 per cent. on the small export at Cette of bauxite from the Hérault, about 10,000 tons during 1910. The Franco-American competition for the supply of the French market at Marseilles in sulphur has become very brisk. The imports of coarse sulphur rose to 58,567 tons in 1910 from 44,274 tons during 1909; refined sulphur from 110 to 627 tons. The prices ruling at the beginning of 1911 have not varied. For pure sublimed sulphur vine-growers are now paying 7*s*. per cwt. Marseilles imported during 1910, 592 tons of wools in bulk, and in skins from the United Kingdom, 265 tons less than in 1909; 7,789 tons from Australia and New Zealand (an increase of 682 tons); 221 tons from India (a decrease of 216 tons). The statistics show that the general importation of wools during 1910 was 22,000 bales less than that of the preceding year, of which 4,000 bales were for spot sale and 18,000 bales in transit. This falling off is not so serious as it looks, as the imports of 1910 are well above the average of the importations of the last ten years. The average prices were slightly higher than those of 1909, and there were only small fluctuations. This firmness of rates and the prompt realisation of the wool has been very favourable to importers, and the year 1910 must be considered as having been satisfactory to all in the wool business. It has been able to show the vitality of the Marseilles market and the importance, often misunderstood, of the local wool-washing industry. Although the financial crisis in America may have prevented orders from that country, and although the Marseilles stock has rarely given to users the opportunity of getting their full supply, Marseilles washers alone have been able to absorb, at prices surpassing those of their opponents, the greater part of the wools imported to this market. An interesting development has within ten years taken place in southern French shipbuilding. The shipbuilding yards of the Chantiers de Provence, at Port-de-Bouc, at the mouth of the Etang de Berre, where at first only dredgers, lighters, and small steamers were turned out, now employ 1,100 men, and have launched vessels of nearly 12,000 tons displacement. Of the total imports, which reach 5,096,628 tons, the British flag comes in for 1,270,767 tons and the French for 1,786,063 tons. The export movement has been less remarkable; the increase only reaches 61,488 tons, an increase of 84,207 tons under foreign flags and a decrease of 22,769 tons under the French flag. The exports under the German flag have increased by 25,645 tons, and the British decreased by 14,099 tons. On the other hand, as to passengers, 1,504 more than in 1909 have been carried under the British flag, and 104 less under the German. The tables indicate a falling-off of 382 ships, but an increase of 632,892 registered tonnage, showing the tendency to increased tonnage of ships. On this quantity the French flag shows an increase of 52,727 tons, and the foreign of 376,916 tons. Shipping under the French flag absorbs 25·33 per cent.; other shipping, 74·67 per cent. of the total tonnage of the port of Marseilles. In spite of competition the port of Marseilles holds its own.

HOME INDUSTRIES.

The Shipping Industry.—Notwithstanding the lock-out of shipyard workers and the closing down of all the federated shipyards at the close of last year, and the series of strikes of seamen and dock and harbour labourers still unsettled, the outlook for British shipping from an economic point of view is more favourable than it has been for many years. The world's trade offers at the moment active and profitable employment to merchant shipping. This trade has been growing, and is still growing, in spite of many restraining influences, and if the world's harvests this year realise present estimates and expectations there will be a still larger movement of international commerce, and consequently a still larger demand for sea-carriers. The cessation of the shipping boom of 1907 has permitted shipping to come more into relation with commercial requirements. During the last three or four years shipbuilding has been so reduced that commerce has had time to grow up to it. There is still an over-supply of certain kinds of ships in certain trades, but much of the surplus tonnage of four or five years ago has been utilised in various ways, and the supply of floating shipping has not been increased within the past twelve months in proportion to the increase of trade. This readjustment of proportions is partly the result of the slowing down of building during the dull years, and partly of delays in building caused by the shipyard lock-out last year, and the amount of traffic to be sea-borne has grown more rapidly than the available tonnage. Further rise in the freight markets may be looked for in the autumn, though that does not necessarily mean that all shipowners are making more money, for working costs have risen and are rising under the demands for increased wages, irrespective of freights. It may be hoped that the present brighter prospect for shipping will not encourage a renewal of the building of steamers on long credit for impecunious owners, who get up small companies and run vessels on credit, regardless of profit, for the sake of the commission they draw on gross earnings.

The Telephone Industry.—On July 27th the National Telephone Company held its forty-eighth ordinary general meeting, which was its last. At the end of the year, as all know, the whole of the telephone system of this country will be operated by the Post Office as a Government institution. We are often taunted, as a country, with our backwardness in the use of the telephone, and there is some ground for the taunt; but, notwithstanding, the National Telephone Company, which has had many difficulties to reckon with, is able to show a fine record of progress. Thus, for the six months to June 30th, 1894, its income was £327,000; for the six months to June 30th, 1911, it was £1,634,447. After deduction of working expenses the balance in 1894 was £140,500; for the past six months it was £576,278. The amount to be put aside for reserve for the six months ended June is about two-thirds of the total net income for the half year to June 30th, 1894. And notwithstanding the approaching transfer, the business continues to grow. During the past half-year 15,675 stations were added to the system as compared with 16,286 stations in the corresponding period of 1910. The income secured in respect of the business of the half year shows an increase of £129,559, as compared with the corresponding half of 1910. The business has increased by practically five times in seventeen years, and the income accrued in respect of this business rose from £738,680 in 1894 to £3,422,423 in 1910. The net earnings for 1894 were £279,176; for 1910, £1,105,572. In 1904 the Company carried to reserve £58,429; in 1910, £375,000. The rentals carried forward for unexpired terms were only £313,979 in 1894; in 1910 they were £1,413,376. At the meeting of July 27th the Chairman was able to say that, in his opinion, the reserve fund has now reached a sum which should be ample to protect the shareholders' capital from any possible diminution in value.

The Cotton Crop.—The American cotton crop conditions appear favourable. Reporting upon the Troy district, Alabama, Messrs. Bashinsky & Co. write, under date July 15th:—"Weather conditions over the greater portion of this section have been perfect during the first half of this month. Showers have been abundant, though not evenly distributed. In many places where rain is still needed, the plant shows some discoloration, but indications point to a continuation of showery weather, and the dry places will, in all likelihood, receive their share of moisture in due time. Fields present a tangle of spreading foliage, and on examination of the stalk a good supply of bolls, ranging in size from half to full grown, is revealed. The season thus far has been conspicuous by the absence of rust or shedding, and if growth is not checked by an early change to prolonged dry weather, good results from the top crop may be expected. But it must be borne in mind that there is but little 'made' cotton as yet. In the present critical stage the plant cannot stand a protracted drought, and any damage from that source would prove irreparable. The Government agent, after a recent inspection of the five infected counties of this State, reports the appearance of the boll weevil less than expected, owing to the pretty thorough destruction of the cotton stalks and cleaning of the fields last fall. He does not think they will suffer more than 5 per cent. damage." The reports from Egypt warrant the hope that the cotton crop in that country will not be below a good average.

Labour Disputes Settlement.—Reference was made in these Notes recently to Sir C. Macara's proposals for the settlement of labour disputes. He explains that he does not suggest interference with the work of any conciliation body that has already been established, but rather the filling in of a gap that exists in the means of bringing together disputants on either side. Referring to Sir S. B. Boulton's description of the origination and proceedings of the London Labour Conciliation and Arbitration Board, and the Chamber of Commerce, Sir C. Macara writes:—"With the fullest acknowledgment of the splendid work undertaken by the chambers of commerce throughout the country, it is undeniable that the great organisations of employers and workmen would never agree to submit their cause, when deadlocks arise in our staple industries, to such a body as Sir S. B. Boulton suggests. The scheme I have proposed suggests the creation of a special department, with a chairman, deputy chairman, and staff, assisted by an advisory body composed of men who have occupied leading positions, on the side of both capital and labour, in the great staple industries upon which our national existence depends, and this tribunal would be requisitioned only when deadlocks arise in the negotiations between disputants in these industries. The proposed new official staff would also deal with disputes in the smaller industries, in places in which no such admirable organisation exists as that of which Sir S. B. Boulton has been so long the chairman. The capacity of the Board of Trade for dealing with the calls upon it, at a time of great industrial unrest such as that through which we are now passing, must be strained to the utmost; and in my opinion an entirely new department is a necessity of the times."

Employers' Liability Insurance.—It has long been known that insurance companies doing this kind of insurance business are greatly dissatisfied with the results, and some of them are considering whether it would not be possible to rate the risks on a more scientific system than that now in operation. In fire insurance, where the tariffs apply to many manufacturing processes, account is taken of the hazardous features existing in premises where the work is carried on, and allowance made for appliances which minimise the risk. In fact, the tariffs embody an attempt to assess each individual risk on its merits. But in employers'

liability insurance a cruder system prevails. The companies do not make a general practice of inspecting the premises where the work is carried on, and few or no questions are asked with regard to hazardous features or conditions in individual premises, or the precautions taken against accidents. It would not be possible to apply the practice of fire insurance companies in its entirety, but it is pretty safe to say that sooner or later the present methods of employers' liability insurance will be modified.

Sulphate of Ammonia and Nitrate of Soda.—The producers of sulphate of ammonia are periodically disturbed by the fear that the demand for nitrate of soda may seriously affect their business, but it would seem that there is plenty of demand for both commodities. The demand for nitrate continues to increase, and during the past twelve months shipments have largely increased—during the last year they have amounted, roughly, to 200,000 tons—but prices continue to tend upwards. Producers are now getting quite sixpence per quintal more than they were willing to accept only a few weeks ago, and at 7*s.* 6*d.* for refined nitrate the better situated producers can earn very substantial profits. The considerable advance in prices which has taken place is also calculated to stimulate the output, but will not, it is thought, more than meet the growing demand. Notwithstanding the steadily increasing shipments, the European stocks show a decline of nearly 50,000 tons as compared with the corresponding date of last year, and a further moderate rise in prices is not at all unlikely.

Linoleum.—The conference at Berlin, held under the auspices of the German Linoleum Syndicate, has led to an agreement which has for its object the maintenance of prices on a stable basis. When the Syndicate was formed at the beginning of the present year, minimum prices were fixed in accordance with the increase of approximately 30 per cent. in the cost of manufacturing linoleum, mainly due to the advance in the price of linseed oil. It is not now intended materially to alter these prices, but the German producers wish to make the agreement between the German and British producers for the delimitation of the territories of the respective groups more rigid. The British makers, however, are indisposed to changes which might, as they think, alarm customers.

NOTES ON BOOKS.

THE VENTILATION OF ELECTRICAL MACHINERY. By W. H. F. Murdoch, B.Sc., M.I.E.E. London: Whittaker & Co. 3*s.* net.

It appears that the amount of literature on the ventilation of machinery is quite out of proportion to the importance of the subject. To a certain extent the efficiency of machinery depends upon the possibility of ventilating it, for one of the reasons for the present high cost of electric generators is the fact that only small rises of temperature are permissible, and Mr. Murdoch thinks there is little reason to doubt that "with the advance of technical applications and artificial local cooling the cost of large generators may be reduced to one-half or one-third of the present cost per kilowatt." In this volume he discusses the effect of increasing the output above the normal on the efficiency of a generator; natural cooling; heating and cooling curves; the ventilating action of an armature and fans; the refrigerator as a cooling agent; practical methods of ventilating motors, etc., and he concludes with a section on data for thermal calculations. The book is a useful contribution to a subject which has not yet received the attention it deserves.

A HISTORY OF ARCHITECTURE IN LONDON. By Walter H. Godfrey. London: B. T. Batsford. 7*s.* 6*d.* net.

Everybody knows that London contains a very large number of beautiful and historical buildings, but it requires an unusually extensive and peculiar knowledge of London to say where most of them are, or to mention their principal characteristics, historical or architectural. The object of this book, as stated by Dr. Philip Norman in a brief introduction, is "to provide the means for the easy discovery of these buildings, and at the same time to give their historical interpretation."

Of course, no attempt has here been made to write a complete history of the architecture of London—that would be out of the question within the limits of such a volume—but a considerable number of buildings have been selected, and in such a manner as to give the various periods their proper relative treatment. Naturally enough, the majority of the buildings described are well known, but to most readers of the book there will be a few pleasant surprises. A useful feature of the volume is a series of maps showing the sites of many of the most interesting buildings, and a list of the buildings contains a few essential particulars as to their chief characteristics and how and when they may be seen. The illustrations, of which there are 250, deserve careful study; among them it is pleasant to recognise several of Crosby Hall, now satisfactorily settled in its new home at Chelsea.

GENERAL NOTES.

THE INSTITUTE OF METALS.—The annual autumn meeting of the Institute of Metals will be held at Newcastle-on-Tyne on September 20th, 21st, and 22nd. The Hon. Sir Charles A. Parsons, K.C.B., F.R.S., LL.D., is acting as chairman of the local committee, and Dr. J. T. Dunn, F.I.C., as honorary secretary. The meeting will open at 10 a.m. on Wednesday, September 20th, when the members will be welcomed at Armstrong College by the Right Hon. the Lord Mayor of the city, Sir

W. H. Stephenson, D.L., D.C.L., and the local committee, after which a series of papers will be read and discussed, Sir Gerard A. Muntz, Bart., President, being in the chair. In the afternoon members will have the opportunity of visiting shipbuilding, engineering, metallurgical, and electrical works in the neighbourhood. On Thursday, September 21st, papers will be read and discussed at a morning session of the Institute, and in the afternoon there will be further visits to works. For September 22nd the Tyne Improvement Commissioners have placed a steamer at the disposal of the local committee for a voyage to the mouth of the river and back.

THE BIRTH-RATE IN FRANCE.—The *Journal Officiel* states that the number of births in France in 1910 was 774,358, as compared with 769,969 in 1909, showing an increase of 4,389 in favour of the former year. The deaths, however, were fewer last year than those of the previous one; being 703,777 in 1910 as compared with 756,545 in 1909. In 1910 the number of births exceeded those of deaths by 70,580, as compared with 13,424 of the previous year. This great disparity is due to the fewer number of deaths last year as compared with that of the previous one.

THE OIL WELLS OF BURMA.—The most productive oil-fields in Burma are on the eastern side of Arakan Yoma, in the Irawadi Valley, in which is the well-known Yenangyaung field, with an average daily output estimated at 56,000 gallons. Oil is known to exist further south and north, but those areas have not been thoroughly prospected. Nine companies, with a nominal capital of about £12,000,000, are actively engaged either in the extraction of petroleum or in the allied industries —such as refining, etc.—and, according to the American Consul at Calcutta, over £4,000,000 have already been invested in the enterprise. This is apart from the number of small native concerns engaged in working petroleum in their hereditary oil reserves. Burma exported 784,852 gallons of kerosene oil during the year ended March 31st, 1910, and 3,852,160 gallons of fuel oil, while her coastwise exports to India proper amounted to 84,280,000 gallons.

THE NETHERLANDS MARGARINE INDUSTRY.—The Netherlands is among the leading European countries producing dairy articles, on account of its excellent natural butter; but its margarine, or artificial butter, is also one of the principal industries of Europe, and was of importance before any other country had begun to manufacture it. In 1871, two years after Mège-Mouries had made his discovery, a Dutch firm bought his secret and established at Oss, in Brabant, the first manufactory of artificial butter in the world. When the secret shortly after became known to the public, a large number of margarine manufactories came into existence all over the Netherlands, principally in places where many cattle were found, so that a large quantity of milk could easily be bought. There are in the Netherlands a score of margarine manufactories, employing about 1,900 workpeople. Of these, five are in Rotterdam, employing 900 men. Dutch enterprise also controls large margarine manufactories in foreign countries, among other places at Antwerp, Brussels, Hamburg, and Cleves. The Dutch law prevents as much as possible margarine being sold under the name of natural butter. The development of the Dutch margarine industry has created an important trade, not only in the product itself, but in all the materials necessary for its production. The trade in raw margarine and neutral lard is concentrated at Rotterdam, as the majority of the margarine manufactories are situated in the southern part of the country.

THE TURKISH WOOL INDUSTRY.—The provinces of Adana and Angora, in Asiatic Turkey, are known for their fine breed of sheep, which annually yield large quantities of excellent wool suitable for the manufacture of carpets. The Adana wool is coarser than that of Angora, which is very fine. The former is preferred in the American market, because it is much longer. Thus, of the 250 tons of wool produced in the Province of Adana in 1910, about 160 tons were exported to the United States, 40 tons to France, and the balance for use in Turkey. The entire yield of wool of the province of Angora is over 1,000 tons per annum, most of which goes over the Anatolian and Bagdad Railway to Constantinople, and is thence exported. About 150 tons, however, are brought by camel to Mersina and shipped to Germany, France, and Austria. With the completion of the new sections of the Bagdad Railway, now under construction, a much larger part will come to Mersina, which will then become an important wool market.

CULTIVATION OF FLOWERS ON FRENCH RIVIERA.—The exports of flowers from the French Riviera has of late years assumed proportions not contemplated even ten years ago. The value of the cut flowers sent away annually from the "Côte d'Azur" may be roughly estimated at fifty millions of francs (two millions sterling). Amongst the principal flowers grown for export in this region, which comprises Grasse, Nice, and Cannes, the carnation takes a prominent place. Of late years a demand has arisen for a strong, rigid, stalked variety, *à tiges de fer*, in place of the old-fashioned kinds with more pliant stems formerly grown. This condition has been met by the introduction of American varieties of the plant. It has been found by careful analysis that the flower stems of these new varieties contain not only a larger percentage of dry substances—nitrogen, phosphoric acid, and potash—than those with less rigid stems, but that they absorb a greater amount of nourishment from the soil. These facts should not be lost sight of in the cultivation of the flower, and in the use of suitable manures.

Journal of the Royal Society of Arts.

No. 3,065. VOL. LIX.

FRIDAY, AUGUST 18, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

INDIAN SUPERSTITIONS.

By M. N. Kurup.

[Sir George Birdwood, by whom the following article was seen through the press, writes on it:—

"Mr. Kurup's paper is well worthy of a place in the *Journal*, and is most valuable as an appendix to the excellent paper on the same subject recently read before the Society* by Mr. R. A. Leslie Moore. The lizard referred to is the omnipresent 'house lizard,' or 'wall lizard,' of the East Indies, as distinguished from the 'garden lizard' of Anglo-Indians; its widest spread native Indian name, in nearly all Indian languages, being *chipki*, with its variants *chipka* and *chipkali;* obviously an imitation of the sudden, sharp, and [seeming] significant cry of this wee saurian; because of which, and its supernatural voracity [for if in appetite it will incontinently turn and devour its own flesh !], and its unavoidable ubiquity, it has been immemorially accepted throughout India, and Farther India, and the Indian Archipelago, as the universal village oracle, and most powerful ally of the *jotishi*, or village astrologer; a special *Shastra*, or Sacred 'Book of Instruction,' the *Gauli Shastra*, quoted by Mr. Kurup, being devoted to the interpretation of its cries, and the actions, accidents, and other incidents of its intrusive and impertinent co-domesticated life, with the simple-minded and kindly-hearted, and devout people of India—India of the Hindus. There is a belief in India, and 'the East Indies' generally, that this lizard causes morphew, a leprous eruption of the skin, and again that an electuary of it is a cure for morphew; and its Arabic name *samibras* [*samm* 'poison,' *abras* (against) 'leprosy'] is founded on this belief. The Greeks and Romans held a similar belief, derived aboriginally no doubt from the East, and then taken back to the East through the Arabian writers on medicine, at second hand from the Greek and Latin writings on plants, "Materia Medica," and natural history. Compare Pliny *N.H.* viii.-49 (32), xxix.-23 (4), and xxix.-38 and 39 (6). In viii.-68 (39) he describes an Indian lizard of the Himalaya [Mount Nysa] twenty-four feet long, and coloured in purple, and yellow, and azure. Mr. Kurup's paper, indeed, presents us, virtually, with the whole contents of 'the Lizard (*Gauli*) Shastra,' and that, 'nota scienter,' is the value, and enduring value of it. Also note well throughout it, the popular Indian dread of 'the police.' His one omission, quite venial, is that he has not sufficiently enforced the fact that the interpretations of the vagaries of the *chipki's* daily life in a blameless Hindu's house, have to be modified by the observer's position in 'the points of the compass,' in relation to the ominous lizard; and by the time of day ['light' or 'dark'], the half of the month ['light' (waxing moon) or 'dark' (waning moon)]; and the period of the year ['light' (spring and summer), or 'dark' (autumn and winter)]; complications that serve the purpose of always justifying the lizard and the astrologer—whatsoever the event. Mr. Kurup's sin of commission is his superior way of sneering [into which he has been betrayed by his English education] at the ignorance of his fellow-countrymen, who still live joyfully with their gods, and in the beliefs of their wise, and wary, and right worshipful forefathers. But I do not press that point: only asking such writers to remember:—

Your laughter has killed more hearts than ever were pierced with swords.
Ever you daub new mirrors and turn the old to the wall;
And more than blood is lost in the weary battle of words;
For creeds are many; but *Truth* is 'One, and contains them all.'"]

* See *Journal*, February 24th, 1911.

It is known to the wide world that there existed in India, in past times, all sorts of so-called superstitions. But it may not be so well known that they continue to flourish not less in number to the present day. But it is some consolation to know that all the educated classes of India are having their eyes opened to the error of these foolish beliefs.

My present object is to bring before readers of the *Journal* a *précis* of the *Gauli Shastra*, which deals with predictions from the falling of lizards and the chameleon. The belief in these predictions is general throughout India, but prevails particularly in Southern India, where the Dravidian Hindus are supreme. The following is an abstract of these predictions as given in the *Gauli Shastra*. I myself have little faith in them; and I send you the whole of them because a good gentleman, who is regarded as a great authority on the subject, professes to have had the truth of some of them demonstrated to his satisfaction. I give the abstract in a tabular form.

If a lizard or a chameleon falls on	the result is :—
Hair	Comfort.
Right cheek	Meeting a friend.
Lock of hair	Illness.
Tip of hair	Loss.
Crown of head	Death.
Forehead	Wealth.
Middle of eyebrow	Loss of wealth.
Right eye	Good to family.
Left eye	Arrest by police.
Mouth	Hearty meals.
Nose	Anxiety.
Right ear	Wealth.
Left ear	Sorrow.
Lower lip	Gain.
Upper lip	A row, or a fight.
Between lip and chin	Death.
Neck	Arrival of a relation.
Right shoulder	Success.
Left shoulder	Defeat.
Hand	Loss of wealth.
Between wrist and elbow	Gain of jewelry.
Back of hand	Loss of wealth.
Finger	Arrival of a friend.
Nail	Loss of wealth.
Palm of hand	Discomfort in family.
Back	Secret information.
Ribs	Meeting of a relation.
Stomach	Wealth.
Breast	Comfort.
Paps	Good luck.
Nipple	Hearty meals.
Armpit	Connubial bliss.
Right hand	Fame.
Left hand	Disgrace, sorrow.
Wrists	Loss of wealth.
Waist	Gain of dress and jewelry.
Abdomen	Illness.
Below abdomen	Fame.
Below that	Death.
Rectum	Illness.
Thigh	Loss of dress.
Knee	Arrest by police.
Below knee	Loss of wife or husband.
Foot	Arrest by police.
Heel	Death.
Big toe	Comfort.
Toes, or toe	Loss of a bow.
Nail of toe	Loss of cattle.
Sole of foot	Ruin.
Bed	Bad luck.
Chair, or chairs	Good luck.
Empty plate	Love.
Cooking pie	Loss of wife or husband.
Temple (or church), while at worship	Death of ruler.
Public meeting	Death of chairman.
Two friends talking	Bad luck for better man of them.
Two persons fighting	Victory for weaker.
Light, extinguishing it	Overwhelming misfortune.
Carriage	Journey delayed.

A lizard falling on the stomach of a wife indicates an addition to the Family.

Also, if a lizard falls on any of the Family five days before Full Moon, it means an addition to the Family; if four days before that, added wealth, as well as an addition to the Family.

If a lizard fall on the Monday, Wednesday, Thursday, and Friday of a week, there will be money in it; if on the Sunday, Tuesday, and Saturday of a week, loss of money.

Lastly, if the cry of a lizard or chameleon is heard from the Zenith, or from due East, West, or North, we shall be successful in whatsoever we may be thinking of, or doing, or whithersoever we may be going; if from the South—the Kingdom of Yama,—Death. The cry heard from South-East means wealth; from South-West, sorrow; from North-East, difficulty; and from North-West, travel in distant countries.

THE LONDON MEETING OF THE INTERNATIONAL SOCIETY FOR THE PROMOTION OF COMMERCIAL EDUCATION.

From July 24th to August 12th some two hundred students took part in this meeting, zealously attending three lectures each morning, and paying visits in the afternoons to factories and commercial undertakings.

The International Society organising the meeting has been mentioned in previous numbers of the *Journal*. Its headquarters are at Berne, in Switzerland; its President, Monsieur A. Junod, is the Federal Inspector of Swiss Commercial Education. The Society is very active in collecting and circulating in its *Review* much valuable information respecting commercial teaching and the progress of commercial education throughout Europe, but it is best known, probably, by reason of the yearly courses of lectures on commerce which it arranges. The London meeting is the fifth of these, the successor of meetings at Lausanne, Mannheim, Le Havre and Vienna. The aim of the meetings is to give a practical course of lectures on the commerce and industry of the country in which the students are assembled; theories and history are excluded, and attention confined, as far as possible, to the existing conditions of trade, to the prevailing methods of business, the commercial prospects, and the industrial developments within a particular sphere—last year within Austria, this year within Great Britain. Next year the meeting will be at Antwerp, and Belgian commerce will be treated from this same practical standpoint.

The London meeting, which closed on the 12th inst., has been in many ways an epoch-making one for the Society. In the first place, it was attended by over two hundred students; one hundred was the largest number at any previous meeting. Secondly, there were representatives in London from countries never before represented. China sent four students; four came from Greece; a Chilian professor was specially sent by his Government; Englishmen were present for the first time, while a New Zealander and a Canadian were also the first to come from their respective countries to the International Society's meeting.

As to the rest of the audience, Germany, Switzerland, and Belgium sent the largest number of students, while Sweden, Norway, Holland, Russia, France, Austria, Hungary, Italy, Finland, and the United States contributed a proportion of the students. About a dozen ladies were present.

In the third place, the London meeting was a new departure in respect to the afternoon visits. These are an important part of the course, illustrating the matters treated in the morning lectures. Never before had it been necessary to break the students up into small parties for the visits. At previous meetings the whole body of students were able to go together to visit commercial undertakings, and some disappointment was at first expressed when the two hundred members of the London meeting learnt that they could not go in a body to the Bank of England, or the Mint, or to the warehouses and factories which were visited. However, the organisers of the course were able to arrange a number of excursions for each afternoon, and generally satisfied the students, though the latter were sometimes in doubt as to their choice of entertainment. On one afternoon, for instance, there were six different parties, and a student had to decide whether he would go to the bindery of the Oxford University Press, or to Messrs. W. & A. Gilbey's wine cellars, or to Pitman's Metropolitan School, or Messrs. Henry Tate & Sons' sugar refinery, or would see the *Daily Mail* printed at Carmelite House, or jam made at Messrs. E. & T. Pink's factory.

Besides the afternoon visits in and around London, excursions were made to Northampton and to Birmingham, where typical factories were visited, and a third day was given up to a river trip from the London Docks to the mouth of the river, and back to Blackwall, visiting the Albert Docks on the way.

This trip was arranged by the Port of London Authority, who lent the "Conservator" for the occasion. The Authority were very good friends to the students throughout, allowing no less than six different parties to visit the warehouses of the London Docks. The organisers of the course were particularly grateful for this, for every student was eager to visit the warehouses, and in the end almost all were accommodated.

Another good friend was the General Post Office. The Postmaster-General was one of the first members of the London committee of the International Society; Mr. Robert Bruce, Controller of the London Postal Service, gave an excellent lecture on the work of the Post Office, and after the lecture six parties of students, about one hundred and eighty in all, visited the General Post Office and the sorting office at Mount Pleasant. The Education Office of the

London County Council also showed a most gratifying interest in the society's meeting; on the first afternoon of the course the students were divided—with no little labour for the organisers—into twelve parties, which paid visits to typical Council schools in Hampstead, in Central London, in the Borough, and even in Forest Hill.

I have mentioned some of the factories which were visited. Messrs. Peek, Frean & Co.; Messrs. Doulton & Co.; and Messrs. Watney, Combe, Reid & Co., also received the students in a most generous manner. The Great Eastern Railway at Stratford, and Messrs. James Carter & Co. at Raynes Park, were also particularly kind, but to the great disappointment of the organisers many of the students missed their train for this last visit, and did not avail themselves of the interesting and hospitable preparations made for them.

Such mishaps were only to be expected; the students gallantly sat through their three lectures each morning in spite of the intense heat; they were generally ready to miss their lunch and rush off to their afternoon's destination, but towards the end of the three weeks' course, some slackening in their zeal was but natural.

However, they all had their share of commercial and industrial sight-seeing, and all expressed their gratitude for the reception they were given on each occasion. What they saw was of the best. The organisers discovered early in their work that only the best factories were ready to admit foreigners without fear or suspicion; they came to know that a refusal was certain from a firm not in the first rank.

No mention has been made of the lectures, as many have appeared in the daily press,* and the Society hopes to publish a collection which will comprise almost all the forty-five that were delivered. The lecturers were foremost men in their particular lines, combining an excellent delivery with first-hand practical knowledge of commerce and industry.

A word may, however, be said as to the lessons of this meeting. Here were two hundred foreign students—there were but half a dozen Englishmen among them—mostly teachers or pupils at the Continental commercial academies, institutes, etc., who willingly sacrificed their short vacation to go through this exceptionally strenuous course. Moreover, many of them do it year after year; those who have been to one of these meetings seldom fail to come regularly in subsequent years to the succeeding meetings. Without entering into any discussion upon systems of commercial education, one may ask whether such a movement as this should not commend itself to all students of business and industry. Can we not find young men in this country whom we may profitably send to the meeting and lectures at Antwerp next year? The International Society was hardly known when it began to organise this London meeting some seven months back. Had it not been for the invaluable start given to it by Sir Henry Wood (of the Royal Society of Arts) it is difficult to see how the meeting could ever have been arranged. Thanks to him, and to a few friends who from the first appreciated the work of the Society, the London meeting was arranged and went off most successfully. But it would be false to pretend that the Society had been well received by commercial societies generally in England. One hopes it is merely that they are conservative, and may still take an active part in the work of the International Society. At the close of the meeting, the delegates of the Society were entertained at lunch by the Government, an entertainment which to some extent brings the British Government into line with the twelve leading Governments of the Continent, which, however, not only patronise but also subsidise the Society. Mr. Tennant and Lord Brassey both spoke favourably of the work of the Society, while regretting the small share which England had hitherto taken in its affairs. The President of the Society, in replying, expressed his earnest hope that at future meetings the young English students would be as numerous as those from Germany and Switzerland. His wish must be echoed by all who are interested in commercial education, whatever their particular theories on that thorny question.

E. Cleveland-Stevens,
Secretary of the London Meeting of the International Society for the Promotion of Commercial Education.

* A report of Mr. Frederick Huth Jackson's lecture on "The Bank of England" appears in the next column.

THE BANK OF ENGLAND.*

By the Right Hon. Frederick Huth Jackson,
President of the Bankers' Institute.

The original charter of incorporation of the Bank was granted as far back as 1694, but the real

* This report of a lecture delivered in the House of the Royal Society of Arts to the members of the International Society for the Promotion of Commercial Education is reprinted, with the Editor's permission, from the *Financial Times*.

history of the institution as it is to-day dates from the Bank Charter Act of 1844, carried at the instance of Sir Robert Peel.. The years immediately before 1844 were years of trouble, and of recurring financial crises; and it is generally admitted that it was partly owing to the failure of the Bank of England Directors to observe a due proportion between their issues and the bullion in their vaults that these crises had been so severe and disastrous. The main principle of the Act of 1844 was the complete separation of the business of issue from the business of banking. The form in which the Bank's accounts, both of banking and of issue, were to be published, was laid down; but while in the business of banking the directors were left complete discretion, the business of issue was strictly regulated, and no discretion was given to the directors at all. As far as they were concerned, the business of issue might have been under the control of the National Debt Commission or any other body of officials worthy of trust. Up to an amount of £14,000,000 notes could be issued by the Issue Department against securities; beyond that amount no notes could be issued except against coin and bullion, of which one-fourth might be silver. I have often heard it said that the limit of £14,000,000 for the fiduciary issue was fixed because it was found that in the year previous to 1844 the amount of notes in circulat on had never been less than £16,000,000, and it was therefore assumed that the limit of £14,000,000 was a safe one. It has certainly proved so. If any of the country issues should lapse, it was provided that the Bank of England could increase its fiduciary issue by two-thirds of such lapsed issues. Under this provision of the Act of 1844 the fiduciary issue of the Bank has been gradually increased to its present limit of £18,450,000.

This Act was a triumph for the advocates of the currency theory over the advocates of the banking principle. At that time, and for many subsequent years, the fight between these two parties continued unabated. The financial crises of 1847 and 1857, following so soon after the Act of 1844, kept this dispute alive; but one does not hear of it any longer, and one is glad to think that, whatever criticisms may nowadays be levelled against this Act, they are no longer questions of principle or theory, but of practice. The Act was to continue in force for a period of ten years, and was then to be subject to twelve months' notice on the part of the Government, and to the repayment of the Government debt of £11,015,100. Acts have since been passed amending the Act of 1844 in certain details, but the main principles of that Act as outlined above have not been disturbed. By this same Act no other bank could issue notes within a radius of sixty-five miles of London, and Bank of England notes were made legal tender in England and Wales. The main criticisms made nowadays against the Bank Act are two. It is first of all maintained that the gold reserve of the Bank is too small, considering the enormous amount of banking deposits of the country. It is suggested, therefore, that the fiduciary issue should be gradually reduced and replaced by gold. It would undoubtedly be a more satisfactory state of affairs if the whole of our note issue were based on gold. But who is to pay for this? It would cost at least 3 per cent. per annum on the amount involved—or £555,000 a year. Among the chief advocates of this idea are some of the joint-stock banks; but I cannot learn that they are willing to bear the cost of it. The Bank already keeps an average reserve in cash against all its liabilities of 40 to 50 per cent.—or about three times more than the joint-stock banks do. As the Bank of England has its own shareholders to consider, it would not be fair that they should be mulcted in this extra expenditure. There only remains the Government. By the Act of 1844 the whole of the profits of the Issue Department of the Bank of England, after making a reasonable allowance for the Bank's remuneration, go to the Government, and from this source it receives an annual income of over £180,000 a year. It would not only have to sacrifice this and incur the above-mentioned additional charge of £555,000 a year, but would also still have to pay the Bank of England the cost of manufacturing and issuing the notes. Would it be unreasonable to estimate the loss to the Government at a million a year? I think not; and I doubt if any Chancellor of the Exchequer would be prepared to face this proposition.

The Use of Cheques.

The fact is that nowadays the circulating medium in this country is not bank-notes but cheques. The best illustration of this is the Bankers' Clearing House returns. The average daily clearings have risen from £11,000,000 in 1868 to £48,000,000 in 1910. What have been the figures of the bank-notes in the hands of the public during the same years? In 1868 the average note circulation was £24,000,000, in 1910 it was £29,000,000, and this in spite of the enormous increase in the wealth and business transactions of the country in the interval. I think the conclusion is obvious: that those who provide the circulating medium should provide its protection.

The second criticism of the Bank Act is that we should adopt some such provision as the Germans have—that the fiduciary issue could be increased, on payment of a certain fine to the Government. I admit that the present position is illogical. It is not, I suppose, disputed that, if a severe financial crisis were again to occur the Chancellor of the Exchequer would indemnify the Bank for exceeding the legal limits of its fiduciary issues. Why, then, not provide some legal machinery for such an eventuality? The only answer is that I do not think that, in practice, it has worked well in Germany. It has resulted in an habitual exercise of this excess power, without any particular regard to the acuteness of the situation. I prefer our own method, however illogical it may be. We have not required to appeal to the Chancellor of the Exchequer for forty-five years;

and I have every hope that we may be able to avoid approaching him for another forty-five years.

I now come to what is, nowadays, the most important function of the Bank of England—its position as provider of the emergency currency of the country. The currency of this country is no longer bank-notes or even gold, but cheques. These cheques are issued against credit balances with the various banks, on which the cheques are drawn, and at times the banks find that the amount of the cheques drawn—especially when dividends are being paid—brings the amount of their item of "cash in hand and at the Bank of England" dangerously low. It is not a question of actual cash, as most of these cheques and dividend warrants are paid through the clearing. The object of the banks, therefore, is not to replenish their tills, but to replenish their balances with the Bank of England. They all of them have large amounts of money lent out on the money market at call. These they proceed, simultaneously, to call in. The borrowers find that the money that one bank calls cannot be obtained from any other bank, and they are, therefore, compelled to go to the one remaining source of supply, the Bank of England. They borrow there practically the same amount that the bankers have called from them. No actual money passes; the whole thing is done by transfer at the Bank of England. Now, that happens every quarter. It occasions no disturbance—except to the money-brokers—and is habitually carried through without the slightest hitch. Subject to certain reservations, the market knows that nowadays it can always get at any time the accommodation it requires from the Bank of England. The rate for advances is now ½ per cent. over Bank rate, while the rate for discount is Bank rate. One can truly say that everybody in the money market can nowadays, directly or indirectly, obtain advances from the Bank of England, provided he can tender the class of security which the Bank requires. It is still thought by many people that the Bank of England fixes the rate of discount. This is entirely erroneous—the Bank rate attempts to conform to what is the actual value of money in this country. The only effective means we have of attracting gold from abroad is by raising the rate of discount.

PROGRESS IN EGYPT.

Each succeeding annual report on the administration of Egypt and the Soudan attracts increasing attention, and this is mainly attributable to the fact that it bears so unmistakably the personal stamp and touch of the Administrator. It is a plain tale of aims and achievements in every department of government, but the detailed records are obviously prepared for submission to the central controlling authority, and the hand of the chief is perceptible throughout; hence the whole story is characterised by a due restraint and sense of proportion, which combine to present a thoroughly harmonious picture on the whole. The effect is far more pleasing and convincing than, for instance, in the case of the Indian Administration reports, where the impression produced is more or less that of a vast aggregate of patchwork, and where any comments or reflections on *la haute politique*, or on some of the chief social, military, or other vexed problems of the day would be rigidly barred. We do not know whether it may not be possible in the future to induce the Indian Viceroy of the day to write an account of his stewardship on every 31st of December, for submission to the British people, but there can be no doubt such a paper would engage public attention and rivet people's thoughts far more effectually than any of the colourless and belated Indian Blue Books at present produced, with so much lingering and travail, whether at Calcutta or Westminster.

In his last report, the late Sir Eldon Gorst plunged, at the very outset, into a highly controversial topic—the foolish and violent manifestations of Anglophobia, which culminated in the rejection of the Suez Canal scheme by the General Assembly, and the outburst in a section of the English press, which professed to see an impairment of British authority and demanded more or less violent measures in consequence. Sir Eldon made a fairly good defence, reminding his readers that it had been proclaimed over and over again, almost *ad nauseam*, that British policy in Egypt is not merely to give Egypt the blessings of good administration, but to train the Egyptians to take a gradually-increasing share in their own government.

From the time of his appointment, Sir Eldon Gorst endeavoured (1) to encourage the Egyptian ministers and officials to take more responsibility and initiative in the affairs of the country; (2) to give the Legislative Council and the General Assembly, although they are not really representative of the country, an opportunity of making a non-official voice heard in matters of importance; and (3) to develop and give powers to the provincial councils, enabling them to be a real factor in local government, especially as regards education. Of these (1) and (3) have shown successful and encouraging results, but both the Legislative Council and the General Assembly displayed, in 1909 and the first half of 1910, an increasing tendency to become instruments of the so-called Nationalist agitation against the British occupation. Anonymous attacks were made on the Government in connection with the budget and the Soudan, and the unreasonable hostility and suspicion displayed in the discussion of the Suez Canal scheme were in their essence manifestations of Anglophobia stirred up by the Nationalist party. Instead of the Legislative Council contributing, therefore, to further the task of government, the aim of the intolerant majority was to render this impossible, and the moderate minority, if there was one, allowed itself to be dominated and extinguished by the extremists, the whole Council thus utterly failing to perform the functions assigned to it in

the constitution devised by Lord Dufferin. The Ministers are, of course, chosen from among the most capable Egyptians, and are better acquainted with the real desires and opinions of their countrymen than the members of a Council who, in reality, represent nothing but the class of wealthy Beys and Pashas, and are, moreover, unable to withstand any spurious agitation manufactured by a few interested parties. Institutions really representative of the people are obviously impossible in a country in which, out of a population of over 11,000,000, only 600,000, or less than 5½ per cent. can read and write.

As to the assassination of the late Prime Minister, and the eventual execution of the criminal, though some unfavourable criticism was heard in England, the time occupied in the various stages of the inquiry and trial happened to be unusually short, i.e., two months. Sir Eldon considered that on the whole it was a most favourable augury for the future of Egyptian justice that it proved itself able, in a matter where immense efforts were made to pervert the course of justice, to deal with the case in a calm and impartial spirit.

Turning to the more material results of administration, we seem to miss some information that might be useful under the head of Railways. It is gratifying to note that the net earnings were substantially larger in 1910 than in the previous year, but it would be instructive to be told how far the mileage of railways has increased during the British occupation, and what further developments are contemplated, for railways, as we all know, are a pretty sure index of national progress.

Under the head of Agriculture, one of the most interesting events was the appointment of a commission to investigate questions connected with the growth of cotton in Egypt, and a noteworthy result of this commission was the creation of a special Department of Agriculture, with the starting of experimental farms and practical schools of agriculture.

Important reforms have also been carried out in the well-known El-Azhar University and other Mohammedan religious institutions, considered to be outside the sphere of the European officials. Hitherto want of support and encouragement from the Egyptians themselves has been a stumbling block to any progress in this direction, but thanks to the hearty support of His Highness the Khedive, and the Legislative Council, the reforms initiated and elaborated by the Egyptian Ministers have been carried through, and the fact that the prejudices and innate conservatism of the old-fashioned type of Moslem have been overcome by methods of peaceful persuasion, is a hopeful sign for further progress.

BUSINESS METHODS IN CHINA.

In his report on the trade of Canton for 1910 Mr. Acting Vice-Consul R. S. Pratt makes some interesting remarks as to European methods of conducting business in China. "Signs are not wanting," he writes, "that merchants and manufacturers in the United Kingdom have succeeded to a considerable extent in revising their ideas of the exploitation of the China market. Until comparatively recently they were content to apply to local firms, acting as their agents, and to supply them with elaborate catologues which, framed for the European market, were practically unintelligible to prospective purchasers in China, and whose only use was to keep the local agent better informed of recent developments at home. What was wanted was an attractive display of samples, with brief descriptions in Chinese if necessary, and competent travellers—not necessarily Europeans—to bring such samples insistently to the notice of native dealers. This is being realised, and certain foreign firms are opening showrooms for machinery and the like in important trade centres, while other firms have for some time past sent foreign travellers, accompanied by good interpreters, to various inland marts, and have found their enterprise rewarded. The use of advertisements, too, is being greatly extended, and few Chinese cities on the main routes do not display an assortment of highly-coloured Chinese posters.

"The native newspapers — the number of which, already considerable, is constantly increasing — afford another excellent medium for bringing goods to the notice of native buyers, and they are well patronised by the sellers of foreign wares.

"A prominent firm is at present making an interesting experiment, the advantages of which it is still too early to estimate, in employing university-trained men, at salaries considerably higher than those heretofore current, to act as agents and travellers. The Oriental is a keen admirer of education, and is quick to discern whether a man is well-educated or not, and it is important that those who come into contact with him should be men that he can respect.

"It should, however, be remembered that the standard of living in China is much lower than in European countries, so that a large proportion of articles manufactured in Europe is quite unsaleable here. Until the development of industries in China has reached a stage considerably in advance of its present one, the market for machinery must be limited to those machines suited for domestic pursuits, or, at the best, very small factories. It is useless for manufacturers to look to China for a market for elaborate agricultural machinery, motor-cars, labour-saving devices in the spinning and weaving trades, etc., as, in the case of motors, there are practically no roads fit for use, while the machinery is quite out of the reach of the Chinese labourer. On the other hand, sewing machines, glass lamps and lampware, patent medicines, cigarettes, condensed milk, etc., find a ready sale, but must be cheap. It is often found that the superior but dearer British article cannot compete with the cheaper one from the Continent, but still less with the Japanese imitation, the first cost

being a more urgent question with the average Chinese than excellence and durability.

"Many manufacturers write to various Consuls in China asking to be placed in communication with some firm likely to be willing to act on their behalf for the sale of their goods. It is, however, but too often the case that the manufacturers expect the local merchants to buy a range of samples or a quantity of their goods to put before the native merchants. The local merchant is naturally unwilling to invest his money in what is necessarily a speculation, and no business results. Manufacturers in the United Kingdom would find that a little more accommodation on their part when new fields are being opened up would produce results more than proportionately favourable."

A FRENCH STATE COMMITTEE ON THE HYGIENIC ASPECTS OF LIGHTING.

The French official Gazette *L'Officiel* for June 16th, announces that a Committee dealing with the Hygienic Aspects of Illumination has been appointed by the Minister of the Interior in France.

The objects of the Committee, as outlined in the announcement, cover a wide ground, including the general effects of illumination on health, the framing of simple rules as to the best means of applying customary systems of lighting to various industrial operations, the nature and causes of short sight and impairment of vision, and their connection with defective lighting conditions, the study of methods of measuring illumination, etc. In investigating these different questions conjointly the Committee should accomplish much valuable work. In the past the difficulty has sometimes been that recommendations on lighting were made by those interested primarily in the physiological and hygienic questions, but without an adequate knowledge of the measurement of illumination or *vice versa*. It is therefore satisfactory to observe that this Committee receives the support of a number of prominent authorities on hygienic matters, gas and electrical engineers, inspectors of factories, and others interested in various aspects of industrial lighting.

Although reference to the question of industrial lighting has been made in the reports of H.M. Inspector of Factories, and in the recent report of the Departmental Committee on Accidents, there can be little doubt that the subject has not yet received as much official attention in this country as it deserves. A great deal of useful work has been done by the Illuminating Engineering Society—quite sufficient to show what an important part effective lighting plays in the conservation of vision and the prevention of accidents, and quite sufficient to warrant us in following the example of France and bringing the whole subject under State supervision.

HOME INDUSTRIES.

The Yorkshire Penny Bank.—For some time past there has been uneasiness as to the position of the Yorkshire Penny Bank, an institution founded in 1859, and doing a very large business on exceptional terms. The bank has a great number of branches in the north, and its clientèle is almost entirely amongst the poorer classes of depositors. The bank suffered, as all other banks have suffered, but in a peculiar degree, from the depreciation in high-class securities, and the collapse of the Birkbeck Bank has led to the withdrawal of deposits on a scale that gave the managers of the bank cause for anxiety. The balance-sheet made up to December 31st last showed that the position of the bank was not entirely satisfactory at the close of 1910, and it has worsened since then. Happily the great banks have come to the rescue, and have agreed to subscribe a sum of £2,000,000 in order to form a new company to be called "The Yorkshire Penny Bank, Limited," having a capital paid up to the extent of £750,000, a reserve fund of £750,000, and an uncalled capital of £500,000, which has provisionally agreed to take over the liabilities and assets of the Yorkshire Penny Bank. A second group of banks have agreed to give guarantees to the new company for a very substantial total, to provide for the possible future depreciation of securities beyond an agreed amount. The old directors will be upon the new board, with additional ones to represent the banks which have come to the rescue, and the members of the staff of the Yorkshire Penny Bank will remain connected with the new bank. It is significant of the soundness of the Yorkshire Penny Bank that the other banks pay for the shares they receive in the new concern a premium of £3 per share. There is no shadow of censure upon the old management. The funds of the bank were invested in the best possible securities, and great judgment was shown in making advances, but by its constitution the bank was bound not to make profits, and consequently it charged too little for its advances and paid too much for its deposits. It was an unusual limitation, but there it was, and until removed had to be acted upon. The result was that not only was the bank without capital, but it was without adequate reserves for times like these when no class of security is safe from depreciation. The arrangement now arrived at puts the position of the bank beyond cavil, and those who have come to its rescue deserve the thanks of the community. But the day of the institutions which have done so much for thrift on the lines of the Yorkshire Penny Bank seems to be passing. The great banks are trying to get into touch with the poorer depositor. Much of the business of the Birkbeck Bank has been taken over by a great banking institution, many others have now interested themselves in the Yorkshire Penny Bank, and it may be expected that other similar institutions will soon cease to be independent entities. The fall in the value of high-class securities is rendering their extinction

inevitable, and the transfer to stronger hands will be to the advantage of the community.

Pit-Brow Women.—The following amendment to Clause 93 of the Coal Mines Bill was carried by only a small majority in the Grand Committee: "No girl or woman other than those employed on or before the first day of January, 1911, shall be permitted to be employed above ground on any mine, provided always that this section shall not apply to any woman engaged in the cleaning of colliery offices, or for any other like purpose." This suggested alteration of the law is strongly opposed by the women and girls concerned, and a deputation of them has been on a visit to London to protest against it. The probabilities point to Parliament rejecting the amendment, and it is to be hoped it will. It is argued by its author, Sir Arthur Markham, and others, that the law prohibiting the employment of women underground ought to be extended to the employment of women above ground on mines, but the considerations which apply to the one case are not applicable to the other. The main argument against the employment above ground is that the work of separating the stone from the coal—the work of the pit-brow women—is hard and unpleasant. Is it pleasanter for the domestic servant to toil upstairs from cellar to drawing-room, with great buckets of coal? The pit-brow work is thus described by a correspondent: "The number of women employed at each pit varies from twenty-five to ninety, and the great majority of them are engaged in sorting coal. In this occupation an endless band from a yard to two yards wide passes slowly along between two lines of workers. It carries coal of different sizes, from cobs to large nuts. It is the duty of the women, as the coal passes, to pick out stones and shale and throw them aside. These workers are stationed on high covered platforms, or really wooden rooms, with more ventilation and apertures than ordinary workshops. As the coal comes up from the pit mouth it is screened by machinery, the slack and small coal being removed before it reaches the women, and as it leaves them it falls into railway waggons on the line underneath, or into tubs." The women work some eight or nine hours a day, except on Saturdays, or in slack times. They begin at six and finish between three and four. In ordinary times they earn from ten shillings to twelve shillings a week, and the workers are more frequently girls than women. No doubt it is a dirty occupation, but collieries vary in dustiness, the workers no longer wear men's clothes, and improved methods and machinery have done much to make the work less disagreeable. And that it is not unhealthy is demonstrable. Dr. Cooke, of Aspull and Haigh, who speaks from an experience of thirty years, says that morally the pit-brow women are at least equal to any class of indoor woman worker, and that physically they are much superior. The coal dust does not appear to be injurious, there is very little sickness among them, and accidents are rare. Many girls who have been forced to leave the mill through ill-health have actually been restored to health on going to work at the pit-head. At one of the pits at Coppal a woman of seventy-one years is still working, and it is believed she has been at "the brow" for over half a century. There are some 3,000 women and girls employed at the pit-brow in Lancashire. About 1,200 are at work in the Wigan district, 1,000 in the Bolton district, and the remainder are distributed in various mining centres in the county. The displacement of so many workers would cause much distress to the families directly concerned, and it is a very serious matter to close to women any respectable employment.

Textile Mill Driving.—Some uneasiness has been caused by the composition of the committee appointed to inquire into the relative merits of electricity and other modes of driving in textile mills. Certain members of the committee are manufacturers of the plant whose merits are to be examined. They will, therefore, be to some extent judges as well as advocates, but a greater difficulty will arise when a manufacturing member of the committee examines the methods of a rival in the same industry who may or may not be on the committee. It is not to be expected that one manufacturer will be ready to give his best technical information to the managing director of another firm, who could hardly be relied upon to limit his use of it to his report only. It is suggested that the difficulty might be got over by arranging that manufacturing members of the committee should only act as witnesses to their own work, leaving the task of collating the testimony of other firms to members who are not in that particular industry.

Two Great Brewing Companies.—The brewing industry has fallen upon evil days. Increased cost of raw materials and increased taxation, coupled with the growing temperance of the nation, have seriously reduced the profits of nearly all the great breweries, but one stands out from the rest in the continuity of its expansion and profits. Messrs. Arthur Guinness, Son & Co., are the largest brewers in the world, and from the outset of their career they have been highly prosperous. For the year 1910-11 the dividend has been raised from 15½ per cent. to 16½ per cent., the increased amount requiring an additional £50,000. An extra £60,000 is placed to reserve, and although £50,000 less is appropriated to depreciation, nearly £33,000 more is carried forward. The net earnings for the past year rose by nearly £100,000, following an increase in 1910 of £149,000. The ordinary capital was duplicated in 1908 by the issue of a bonus of 100 per cent. in stock, so that on the basis of the former capital the present dividend is 33 per cent. The ordinary stock is quoted at 445, at which the yield to a purchaser is only a trifle over 3⅝ per cent., allowing for the increased dividend. The nearest English brewery in importance to the great Irish concern is

that of Messrs. Bass, Ratcliff & Gretton, but although its position is very strong it has not passed in the same triumphant way through the troublous times. In a prospectus issued in January 1888, it was stated that the audited profits during the five years to December 1887 showed average annual net profits exceeding £340,000. In the past four years the average works out at about £275,000 per annum, but for the year ended June 30th last, the net profits were £295,773 as against £278,578 for the preceding year. In 1908 it was considered wise, having regard to the proposals affecting the trade, and the serious position arising therefrom, to write off from goodwill the sum of £560,000, reducing it to £800,000, this being taken from the reserve, and in view of recent legislation the directors have caused the whole of the licensed properties and loan securities of the company to be valued, and the amount written down under this head is £503,077 19*s.* 8*d.*, which has also been transferred from the reserve fund. The "B" debenture stock yields, at the current quotation of £70, £5 0*s.* 4*d.*, and the preference stock at £92, no less than £5 9*s.* 2*d.* per cent. An increase of 1 per cent. is made in the ordinary dividend this year, making the distribution 8 per cent., and probabilities point to a further increase in the dividend next year.

CORRESPONDENCE.

IMPERIAL COLONIAL DEVELOPMENT.

Captain Collins has sent me a copy of the *Journal of the Royal Society of Arts* of April 14th, 1911, containing his paper on Australia. I know Australia from north to south, and east to west, having done a two years' overland trip there.

I noticed in the *Journal* a letter, written by Mr. C. R. Enock, F.R.G.S., which interested me greatly.

I cannot agree with the policy that Mr. Enock advocates, viz., the granting of Crown lands to British municipalities. To make a grant of land, however fertile, for the purpose of settling British artisans on it, especially in the far-off northern territory, would be to court failure. To be a farmer requires an apprenticeship just as much as any trade.

A British municipality would stand a very poor chance of establishing a successful colony in the northern territory, unless they had the help of a great number of expert Australians.

Those who emigrate at present mostly start work on well-established Australian farms, and thus become acclimatised under the best conditions. New South Wales, Queensland, and West Australia, have well-organised systems of immigration, and it would be very unwise for even British municipalities to try to improve on them. Mr. Enock thinks that present conditions of emigration are too hazardous. For the sum of fourteen guineas a person is conveyed a distance of thirteen thousand miles, and fed and housed for forty-two to fifty days. There is really nothing very hazardous about that when you are placed in a civilised country at the end of your journey—yes, and a country where a man who is adaptable can make a decent living. Contrast this with the really hazardous undertaking of emigrating forty years ago.

Australia welcomes all; there is room for millions; money is not required; grit and determination are the only essential qualifications.

ALAN G. REID.

Obuasi, Ashanti, Gold Coast Colony,
July 13th, 1911.

Mr. Enock, to whom the foregoing letter has been submitted, writes in reply:—

It is evident that Mr. Reid has not grasped the purpose I advocate in the endowment of our British municipalities with areas of Colonial lands, just as others have not. No one with any knowledge of the subject would propose the implanting on the northern territory of Australia, or anywhere else, of inexperienced people, and expect them to work out their salvation by cultivating the soil. The purpose is to allocate such areas of territory in order that they may be a tangible property for British ratepayers; to be developed scientifically and systematically in their interests, forming a field of activity for their surplus workers under organised conditions—not only land-workers, but artisans—centres which would work in conjunction with the parent centres at home, who would establish them. It is to future generations as well as to that of to-day that this benefit would accrue.

As to emigration being hazardous, Mr. Reid states that emigrants can reach Australia for fourteen guineas. But the great bulk of our poor class, who would be benefited by emigration, never had fourteen guineas in their lives! Further, what are they to do when they get there, under present conditions? It is useless to send them out haphazard to flood colonial labour markets. It is all very well to say that Australia is a country where a man who is adaptable can make a good living, but the great bulk of our poor and workless are probably not adaptable, or not without proper organisation. They are valuable assets of labour, for whom there is not sufficient scope under present conditions, but who, under organisation such as that of which my proposal forms part, would be producing units. As I have pointed out in the last of a series of articles in the *Review of Reviews*, August (*q.v.*), legislation at home now is favourable to the "back to the land movement." And Canada and Australia are not likely to obtain in the future a large supply of our land-working people. It is therefore to the benefit both of the colonies and the homeland to set about making organised use of the surplus town element. I have gone into the matter in my forthcoming paper this month before the British Association.

C. REGINALD ENOCK.

Northwood, Middlesex, August 9th, 1911.

CANTOR LECTURES ON "ETCHING."

I think it only right that some protest should be made concerning Mr. F. Wedmore's Cantor Lectures on "Etching," printed in the *Journal* of the 11th inst. These lectures are supposed to be delivered by authorities on their subjects. I am totally unaware upon what grounds Mr. Wedmore has any claim to be considered an authority. He is not an etcher—and he proved by the lectures he delivered that he knew little historically. The person who would devote half a page of the *Journal* to Bega—of whose etchings I am blankly ignorant—while dismissing Piranesi and Van Dyke in four or five lines, has a quaint idea of things; but as he has omitted Callot altogether his historical knowledge is quainter. But that does not equal his ignoring Turner, whose name is never mentioned. After that his critical conclusions and contentions and appreciations have little value.

But there is still less excuse for the list of moderns he sets up for us to admire, and no excuse for his omission of many of the most eminent modern etchers altogether—except ignorance, carelessness, or prejudice. The man who influenced modern French etching more than any other was Maxime Lalanne, and his name is never mentioned. Nor are the names of Louis Legrand—the most brilliant etcher in France to-day — nor Paul Renouard, or J. L. Forain; and, in colour, Raffaelli, who has taught people in this country all they have not understood, nor Marie Cassatt, who does understand how to manage it.

The man who to-day is recognised as the greatest etcher in his own country—and this verdict is repeated everywhere else—Bauer, is not referred to, nor Van s'Gravesande either. In Belgium, Rops is omitted as well as Baertoen. In England, I fail to find the names of Sir Charles Holroyd and F. E. Spence in pure etching, Laurenson in colour, and where is Mr. Augustus E. John? Duveneck might as well never have lived if we depended on Mr. Wedmore, and there are at least three other Americans who should be mentioned if MacLaughlin is—C. Harry White, H. Webster, and C. A. Platt. The omission of my own name I can endure with equanimity, for that was not due to ignorance. The only claim that Mr. Wedmore may possess—as authority—that I am aware of, is as the compiler of a catalogue of Whistler's etchings, completely superseded—in the opinion of everyone who knows save himself—by those of Howard Mansfield and the Grolier Club. He, however, still believes in it, and refers to it in his article on Whistler in the new edition of the "Encyclopædia Britannica" and ignores the others. I looked his article up the other day and found in it a round dozen appalling blunders. Reproductive etching is beneath his notice, and therefore the work of William Hole, Unger, and Waltner.

NOTES ON BOOKS.

IMPERIAL TELEGRAPHIC COMMUNICATION. By Charles Bright, F.R.S.E., M.Inst.C.E., M.I.E.E. London: P. S. King & Son. 3*s*. 6*d*. net.

This volume consists for the most part of reproductions of various papers, addresses and articles contributed during the past ten or eleven years to the British Association, the London Chamber of Commerce, and several of the leading reviews; and the immediate occasion for their republication was the recent Imperial Conference. The subject is one of very great importance, both from the commercial and the strategic points of view; and probably no one is better qualified to speak upon it than Mr. Bright, whose interest in it may be said to be hereditary, for it was his father, Sir Charles Tilston Bright, who laid the first Atlantic cable in 1858.

Throughout these pages Mr. Bright has two principal objects in view: to secure a reduction of the rates for cablegrams and to establish all-British telegraphic communication throughout the Empire. The first was one of the points considered by the Cable Communications Committee of 1901, and their suggestion to establish a system of deferred rates is the only one of their recommendations which has up to the present been acted upon. But an appendix to this volume containing a table of charges for foreign and colonial telegrams shows how extraordinarily costly it is to cable to some parts of the world, and to some parts of the British Empire: *e.g.*, the rate to British Guiana is 7*s*. a word. A rate such as this must be practically prohibitive, for, of course, as Mr. Bright remarks, when the tariff is high the traffic is correspondingly low. The defects of the telegraphic systems in the West Indies were thoroughly discussed by the Royal Commission on Trade Relations between Canada and the West Indies, and they were so striking that in their report the Commission recommended a policy of Government expropriation.

While it is not easy to over-estimate the value of reasonable tariffs, not only for commercial purposes but for binding the distant parts of the world together by the rapid dissemination of news, etc., the strategic importance of the cable to an Empire scattered all over the face of the world is even more vital. At present our cables to the Cape touch on foreign territory at more than one point, and even the all-British Pacific cable has to depend on the Atlantic Cable Companies for the transmission of messages between Canada and this country. The necessity of being able to keep our communications with India untapped by any foreign Power must be obvious to everyone.

While Mr. Bright would be content to leave international cables in the hands of private companies, he is strongly of opinion that strategic lines, at all events, come within legitimate Government scope, and he advocates the establishment of a new board of control, or authority, to deal with these

matters. The Colonial Office, which might be supposed to be primarily interested in the question is, in his opinion, too much "over-ruled by the department with the purse-strings on the one hand; and, on the other, by a technical department which has practically nothing to do with our over-sea dominions or with the technique or administration of *ocean* telegraphy."

With regard to the form of the volume, objection may be raised on the ground that as the various papers composing it have been written at intervals spread over eleven years, and as there have been considerable developments in telegraphy during that period, it is necessary, when reading each article, to bear in mind continually the exact date at which it first appeared. There are, doubtless, some drawbacks in this, and Mr. Bright has evidently been conscious of them himself, for he has made a statement in a preface of the most important developments which have taken place since the dates of the various articles. But, regarded historically, this arrangement has its advantage, for it enables one to follow from contemporary documents the exact history of the industry. In any case the book is extremely interesting, and it deserves the careful study of business men, statesmen, and strategists.

Office Procedure and Business Correspondence. By H. Clemson. London: Butterworth & Co. 2*s*. net.

Methods and Machinery of Business. (Second Edition.) By H. Clemson. London: Butterworth & Co. 2*s*. 6*d*. net.

These two volumes are designed as handbooks for students preparing to enter for commercial examinations. The former is of an elementary nature; the first seventeen chapters are devoted to letters, messages, goods, and simple accounts, and are recommended as a first-year course in schools where much time cannot be given to commercial work. The second part deals with bills of exchange, security, international commerce, partnerships, companies, etc., and is adapted to a second-year course. The volume contains an article on Life Insurance, by Mr. J. Burn, and another on Railways, by Mr. W. Brazier Martin.

"The Methods and Machinery of Business," which has reached its second edition, is of a more advanced nature, and is intended more especially for clerks in shipping departments and students entering for higher commercial examinations. It is divided under four main headings: inland and foreign exchange, marine insurance, fire and life insurance, and stock exchange. The author has added a fresh chapter, in which he reviews the various causes of the fluctuations in the market price of Consols, and criticises the suggestions recently put forward with the object of raising their price.

Mr. Clemson has had considerable experience as a teacher of commercial subjects. He writes in a clear and simple style, and the illustrations which he has introduced of bills of lading, bills of exchange, invoices, contract notes, broker's tickets, etc., should be useful in familiarising the young clerk with documents of this description.

GENERAL NOTES.

The Foreign Trade of France.—The total value of the exports and imports of France during the first six months of the present year, notwithstanding that they show an increase of 771,386,000 francs (£30,863,440) over that of the corresponding period last year, is not by any means as satisfactory as it may appear at first sight. From the following figures it will be seen that, whilst the value of the imports show an increase of 843,174,000 francs (£33,726,960) during the first half of this year, that of the exports has fallen off by 71,588,000 francs (£28,635,200):—

	Value of Exports (in 1,000 francs). 1910.	1911.	Difference in + or −
Food stuffs	431,113	334,931	−96,182
Raw materials	969,702	951,478	−18,224
Manufactured goods	1,451,251	1,497,980	+46,729
Postal parcels	244,634	240,733	− 3,901
	3,096,710	3,025,122	−71,578

	Value of Imports (in 1,000 francs). 1910.	1911.	Increase.
Food stuffs	563,123	1,141,125	578,002
Raw material	2,304,219	2,518,702	214,483
Manufactured goods	700,976	751,665	50,689
	3,568,318	4,411,492	843,174

This falling off is particularly noticeable in the enormous increase in the value of the food stuffs which it has been found necessary to purchase abroad, in order to make up the deficiency caused by last year's bad harvest.

Anchovy Fishery at Cannes.—The anchovy fishery on the French Riviera has been, on the whole, very successful during the past season, the catch generally being above the average. According to the returns of the inspector of fisheries on this coast, the quantity of this fish sent by rail from Cannes during the month of June last amounted to 175 metrical tons, as compared with 170 metrical tons during the corresponding period last year. The fish is salted and packed at the various establishments for the purpose in the neighbourhood, and especially at Cros-de-Cagnes, from which place sixty-five tons were exported to Germany, this being the first time that anchovies have been sent from the Cannes district to that country. The prices obtained this season have been higher than usual, and have reached 75 centimes per kilog. (about 3½*d*. per lb.), as compared with 50 cents. per kilog. (about 2¼*d*. per lb.) in 1911.

NOTICE.

CANTOR LECTURES ON "THE APPLICATIONS OF ELECTRIC HEATING."

The Cantor Lectures on "The Applications of Electric Heating," by Professor J. A. Fleming, M.A., D.Sc., F.R.S., have been reprinted from the *Journal*, and the pamphlet (price one shilling) can be obtained on application to the Secretary, Royal Society of Arts, John Street, Adelphi, W.C.

A full list of the Cantor Lectures, which have been published separately, and are still on sale, can also be obtained on application.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

BREWING AND MODERN SCIENCE.

By Professor ADRIAN J. BROWN, F.R.S.

Lecture I.—Delivered February 6th, 1911.

INTRODUCTION.

The last course of Cantor lectures on the subject of the brewer's art dates as far back as the year 1873. Towards the close of that year my distinguished predecessor, Dr. Charles Graham, commenced a course of seven lectures "On the Chemistry of Brewing," which most deservedly attracted the attention of the brewers of this country. The period when these lectures were given marked the commencement of a new era in the history of the brewing industry, for it was at a time when the growth of scientific knowledge had reached the stage at which it first gave promise of illuminating some of the complex problems of the brewer. The progress of science from the beginning of the century had been extraordinary, and many of our arts and manufactures had benefited widely from its advance long before brewing shared in its benefits. It was not until the value of Louis Pasteur's epoch-making discoveries in fermentation began to be recognised about the year 1870, and the results of O'Sullivan's earlier investigations of starch transformation became known in 1872, that science was in a position to contribute material assistance to the art of brewing. Thus it came about that Dr. Graham, through his well-known course of Cantor lectures in 1873, was enabled to proclaim to the brewers of this country that science was making advances which should prove useful to their industry. Undoubtedly other chemists than Graham, such as O'Sullivan and Horace Brown, had previously turned their attention in the same direction, with the consequence that the more recent advances of science had already been recognised and utilised in some few breweries of the country, but it must ever remain as an honour to the memory of Dr. Graham that his lectures first directed the attention of brewers at large to a serious consideration of the scientific aspect of their industry.

Thirty-seven years after the delivery of Dr. Graham's memorable course of lectures, I have been asked again to review the position of science with regard to brewing. I approach the task with diffidence, feeling that it might with advantage have been placed in much abler hands. In one respect only can I claim to possess any good qualification for the task; it happens that the date of Dr. Graham's first lecture coincides almost exactly with the date of my introduction to practical brewing, and my first unassisted mashing operation was conducted when Graham's course of lectures was in progress. As I have continued to be intimately associated both with the technical and the scientific sides of brewing ever since, I may claim that I have at least been granted an opportunity of watching the progress of brewing and of the sciences bearing on it from the date of Dr. Graham's lectures until the present time.

In one respect, at least, Dr. Graham's task was less difficult than mine, inasmuch as he had the opportunity of expounding his views of a comparatively undeveloped subject in seven lectures; whilst the exigencies of present rapid life allow me only four lectures in which to treat the same subject grown to gigantic size. At the time Dr. Graham gave his course of lectures, his subject was not only a restricted one, but it also was quite new, and he was favoured with an audience eagerly awaiting enlightenment in the very elements of science relating to their industry. To-day things are greatly changed—scientific knowledge has increased to vast proportions, and brewers may justly claim that no industry in this country can exhibit a better record of the recognition and use of this knowledge than theirs. The leaders of many of our industries are often charged with ignoring or overlooking the benefits which science is able to confer; but however true this may be of some industries, it is not so with brewing. Almost every brewer to-day avails himself to some extent of the assistance of science, and but rarely does he refuse to listen to anything science may have to suggest for his possible benefit. No doubt, as a shrewd man of business, he is inclined at times to ask disconcerting questions of the apostles of science with regard to the limitations of their knowledge—but, whatever he may say, the conduct of his business supplies ample evidence that scientific truths, when properly substantiated, are valued by him and made use of. The brewer of the present day not only makes use of science, but is himself often well versed in science as it relates to brewing. To-day he commands useful books on the subject—his technical journals specially devote themselves to keeping him posted in all the more recent advances in the subject—and he possesses an institute devoted to furthering its progress. Thus conditions have changed very much since Dr. Graham gave his course of lectures in 1873, both with regard to the development of the subject, and to the manner in which it is desirable to lay it before an audience. I feel that the time has gone by for any good object to be served by lectures on the elements of science in relation to brewing of a similar type to those given by Dr. Graham, for it would be telling an old tale to the majority here present; on the other hand, when considering how to treat my subject to the best advantage, I am met by the very great difficulty that, owing to its vast extent, it is impossible to deal comprehensively with it even in a much longer time than I have at my disposal. Under these conditions, in order to meet the difficulty to the best of my ability, I propose to select a few representative branches of my subject which possess special interest, and endeavour to show how our knowledge of them has progressed from Graham's time until now, and in what direction scientific investigation is at present leading in connection with them.

But doubtless there may be some in this room, not very familiar with the technical or the scientific aspects of brewing, who may find some difficulty in realising the complex nature of the problems which meet the brewer when he attempts to master the inner working of his processes. A brief glance at the general methods of brewing procedure will, however, demonstrate how the processes are a sequence of bio-chemical changes of the most complex character.

The brewer's objective is to prepare a fermented beverage from barley or other starch-containing grain. His processes, no doubt, originated in ages past through the desire to imitate the production of wine in lands where the grape was not found. The making of wine from the grape is a very simple technical process—the juice of the fruit provides the sugar-containing fermentable liquid, and the skins of the fruit supply the yeast capable of fermenting the sugar: thus crushing the fruit and leaving the crushed mass to stand, results in the production of wine. But it is only by the means of methods involving many complex bio-chemical changes that the brewer can obtain a fermentable liquid from the insoluble starch of grain.

Having selected some grain, such as barley, suitable for his malting process, he proceeds to steep it in water in his cistern in order that the life of the seed, which is dormant in the germ when in the dry state, may be summoned into activity. Then he spreads his moist grain on the floor of the malt-house at a suitable temperature for germination, and awaits the vital processes which ensue as the embryo plant which is contained in each seed commences to develop. Now we must imagine the complex bio-chemical actions which proceed as germination takes place. The germ of the corn gains energy by respiration, absorbing oxygen from the air and utilising it for the combustion of a small portion of the carbohydrate or starchy material with which the corn is so well stored. At the same time, complex digestive changes commence in the corn through the intervention

of enzymes, such as diastase, which are produced during germination for the purpose of dissolving the starch and other constituents of the grain, converting them into suitable food for the growing germ. On the malting floor, as the barley germinates, we are, therefore, witnessing a series of bio-chemical changes of extreme complexity, many of which most intimately concern the purposes of the brewer. But growth of the grain on the malting floor must be allowed to proceed only to a limited extent, otherwise too much of the contained starch from which the brewer ultimately obtains his fermentable sugar will be digested and used as food by the growing germ. Hence, after the grain has grown for a limited time on the malting floor, it is taken to the malt-kiln, where it is dried and "cured" in a current of hot air, in order that its growth may be completely arrested.

As the malt, after being dried in this manner, contains starch together with the digestive enzyme diastase, the starch of the malt is in a potential condition for conversion into fermentable sugar when placed under suitable conditions. These conditions are fulfilled in the subsequent mashing process of the brewer. In this process the previously crushed malt is mixed or "mashed" with water at a temperature of about 65° C. (149° F.), when conversion of the starch into sugar—which would have taken place within the corn if germination had not been restricted by drying on the malt-kiln—now takes place in the mash-tun. Therefore, the complex action of starch transformation during the mashing process, although it proceeds at a temperature inimical to life, may be classed as the continuation of a bio-chemical action.

The solution of sugar and other materials derived from the malt, termed by the brewer "sweet wort," after being run from the mash-tun, is then transferred to a vessel in which it is boiled together with hops. Boiling is necessary for the purpose of coagulating and removing from solution the diastase and certain other protein constituents present in the sweet wort, and also in order to sterilise completely the liquid. Hops are boiled with the wort mainly for two reasons—the agreeable bitter flavour conferred on the beer by their use, and for the purpose of extracting certain constituents possessing preservative power which tend to keep the resulting beer sound.

The boiled wort, after leaving the brewing copper, is subsequently cooled to a suitable temperature of about 15° C. (59° F.), and is then run into so-called fermenting vessels. Here active yeast from a previous brewing is introduced, and the wort commences its primary fermentation, which eventually converts it into beer. This process again introduces us to bio-chemical actions of a most remarkable and important character. During fermentation we have to deal not only with the decomposition, or fermentation, of the sugars present in the wort by the action of the enzymes existing in the living yeast cells, but we have also to deal with the increase or multiplication of the yeast cells and the influence of this on the removal of nitrogenous material from the beer, a matter of fundamental importance in brewing.

In technical practice there are several different ways in which the primary fermentation of the brewer is conducted, but in principle they are all the same and involve fermentation by the addition of yeast and subsequent removal of the increased yeast crop from the final beer. But termination of primary fermentation by no means closes the bio-chemical history of beer. At the conclusion of primary fermentation beer is a flat, lifeless liquid, not the sparkling beverage charged with carbonic acid gas ordinarily recognised as beer. In order to obtain such, it is necessary for a slow secondary fermentation to take place in the beer when it is in cask or bottle, in order to produce the "condition," or sparkling gaseous state which is required. This change again introduces us to biological problems of the utmost importance which are concerned with the development of secondary yeast-growths in beer, about which at present there is still much difference of opinion.

However, I think I have said enough now to demonstrate even to those but slightly acquainted with the bearings of scientific knowledge in relation to brewing, that the study of the science of brewing is essentially a biological study, and that, like all studies which concern the functions of life, it therefore presents problems of extreme complexity.

Barley.

In the past, no doubt, the brewer—more particularly when he was not his own maltster—was too apt to regard malt as the primary basis of his manufacture, and was inclined to overlook many important questions concerning the barley from which his malt was made. But to-day, I believe, every brewer recognises to what a vast extent his welfare depends on the quantity and quality of the barley supply—and, recognising this, he

has also begun to recognise that his interests and those of the agriculturist, the producer of the barley, are most intimately bound together. But this fact has been, and is still—I regret to say—far too often overlooked by the agriculturist, with the result that the great industries of agriculture and brewing are estranged in a manner which is altogether undesirable. I fear, although I may be accused of undue bias, that the agriculturist must be regarded as primarily responsible for this, for when considering his present position with regard to brewing he overlooks certain very evident facts, and imagines things of the brewer which have no reality. In the past, under different economic conditions and under very different excise laws, the agriculturist was accustomed to regard the brewer as an ever-ready purchaser of his malting barleys at prices of a highly remunerative character; at present, under altered conditions of business and under altered excise laws, he finds the brewer a less ready buyer at reduced prices; and the brewer is held to blame by the agriculturist for this result, and not the altered conditions which have been forced upon the brewer much against his will. The agriculturist appears to overlook altogether the fact that the crude and wasteful methods of brewing employed in the past are not possible now under present altered requirements, and under the heavy load of taxation which brewing is now compelled to bear; brewing as an industry must have ceased to exist years ago unless its methods had been accommodated to altered conditions. Increased knowledge has enabled the brewer to obtain better extracts from his malts than were obtainable years ago; it has taught him how to make use of barleys which could not be malted with advantage under the incidence of the old malt-tax; lighter gravity beers, requiring less malt for their production, are brewed now to meet the public taste, and no doubt also to some extent—but one usually much over-estimated—other grain than barley is employed in brewing under sanction of the Inland Revenue Act of 1880. All these conditions may have tended to diminish the consumption of home-grown barley, or to lower its market value to some slight extent, but they are entirely beyond the brewer's control. They have been forced upon him against his wish, and at a time, too, when the general public demand a better, a brighter, and a more stable beer than they were accustomed to years ago. I consider that the brewers of this country have every reason to be proud of the achievement of producing sounder, better, and more wholesome beer for the public use during a period when their industry has had to struggle against the effects of repeated increases of taxation. The task has been rendered possible only by an intelligent use of science — and the generous reward for enlightened progress has been further invitations of a pressing character to contribute more to the public exchequer, and a free circulation of the baseless accusation that improved methods of beer production are obtained by unfair means. I do not regard agriculturists as the authors of this accusation, but perhaps some of them are too ready to believe it, because it may appear to further their efforts in the impossible direction of putting back brewing into the place it occupied years ago. Concerning the accusation itself, I need only point out that breweries are under the inspection of Inland Revenue officials night and day, and that it is the duty of these officials to take account of all the materials the brewer uses, and to supervise all his processes. What other manufactured alimentary product than beer possesses a guarantee of purity such as this? It is unjust for the agriculturist to cast blame on the brewer for any depreciation in the value of his home-grown barley, and it is hopeless to attempt to bring back the past. The interests of the agriculturist and the brewer must always remain most closely associated, and if only this were better recognised much might be achieved for their mutual benefit. In Denmark we have an instance of practical good achieved through a systematic study of barley from the combined points of view of agriculture and brewing. In Ireland we find another instance. Why should we not have something similar in this country in the place of misconception and hard words, which in themselves are not only useless but actually harmful? If, in the brief sketch I propose to give of the progress of our knowledge of malting barley from Dr. Graham's time to the present, I should say anything which tends to bring the interests of agriculture and brewing together ever so little, I shall indeed feel very pleased.

Thirty-seven years ago, when Dr. Graham delivered his course of lectures, our knowledge of the various kinds of cultivated barley was very limited. The different types of barley had been classified by botanists and, of course, agriculturists and maltsters were in possession of a very considerable amount of empirical knowledge concerning them, but no one up to that time

appears to have made any serious attempt to study them scientifically. Apart from the fact that knowledge, perhaps, was hardly ripe for this, there was not the inducement then, as now, to take a wide interest in barley. Before the abolition of the malt-tax in 1880, the number of different kinds of barley which could be used by the maltster with advantage was comparatively small, owing to the fiscal conditions under which the maltster worked. After these conditions were changed in 1880, the maltster was enabled to malt any class of barley suitable for brewing purposes, and, as a consequence, the demand for a more extended knowledge of barley arose.

Almost the only reference to barley in relation to malting in Dr. Graham's lectures is contained in the single remark that it should be grown on a light soil and should contain a large amount of starch. This must not be taken as accurately defining the knowledge of the time, but such a very brief reference to barley in a comprehensive course of lectures on brewing indicates that the subject was not regarded by brewers of the day as one of great importance.

The first distinct advance in our modern knowledge of barley may be traced to Körnicke, of the Academy of Agriculture of Poppelsdorf, who published a monograph on barley in 1882. This was followed in 1885 by the publication, in conjunction with Werner, of a still more comprehensive work, in which all the then known varieties of barley were described, together with the results obtained when cultivating them on the experimental plots of the Academy. But Körnicke's work was carried out and described in Germany, and little or nothing was known of it in this country outside the circle of professional botanists, until it was brought into general notice by E. S. Beaven, of Warminster. So far as this country is concerned, Beaven is unquestionably entitled to be called the father of our modern knowledge of barley; it is his work, his publications, and his enthusiastic support of any inquiry relating to barley, that have mainly contributed to the recent advance in our knowledge of the subject.

Beaven's first important communication on barley was made in a paper written in conjunction with Munro, and published in the *Journal of the Royal Agricultural Society* in 1900. In this paper the different types of barley cultivated in England are described, and it also contains an account of the results obtained when growing a number of different types of barley on experimental plots at Warminster. But it is to Beaven's well-known paper on "Varieties of Barley," published in the *Journal of the Institute of Brewing* in 1902, that we must look for a work which has become a standard for all agriculturists, brewers and others in this country who are interested in malting barley.

Beaven's paper is divided into two sections—in the one he classifies and describes all the known types and varieties of barley, and in the other he discusses them from the maltster's point of view. A very brief summary of this paper, although so well known, will not perhaps be out of place here as an aid in demonstrating the position we now occupy with regard to our knowledge of barley.

Beaven adopted, in the main, Körnicke's system of classification of barley, which is

A. B.

FIG. 1.—TWO-ROWED BARLEY.

A. Broad-eared barley (*Hordeum zeocriton*) with short jointed rachis.

B. Narrow-eared barley (*H. distichum*) with long jointed rachis.

simple and easily understood. It is based on the position and character of the flowers of the barley plant which produce the seed.

The flowers are situated, as is well known, on the stem of the ear of barley termed the rachis. If we examine the rachis of an ear of common barley from which the corns have been removed, we find that it is a flattened stem with joints on each side of it placed not opposite to each other, but alternately. Now the flowers of the barley plants spring from these joints, and the slide shown on the screen represents the appearance of the flowers springing from a single joint of an ordinary two-rowed barley. They are three

in number, as is the case with all the forms of barley with which we are concerned, but the central flower is much larger than the two side flowers. If we could examine the constitution

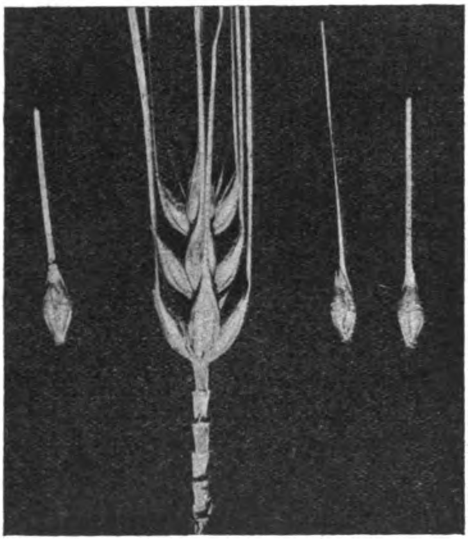

FIG. 2.—SIX-ROWED BARLEY (*H. vulgare*).

of these flowers more closely, we should find in the present instance that the central flower is the only one which is fully developed and possesses an ovary capable of forming a seed—the two outer flowers are merely abortive ones. Consequently, after fertilisation and seed development, a single row of corns only would be found on each side of the rachis of this type of barley, and in this manner what is ordinarily known as a two-rowed barley is constituted (see Fig. 1). But, on the other hand, there is a type of barley in which we find that all three of the flowers on each joint of the rachis are fully developed and each capable of forming a seed (see Fig. 2). Under these conditions, after fertilisation and seed development, we find three rows of corns on each side of the rachis, and this constitutes what is known as a six-rowed barley.

From the position and character of the flowers of different types of barley we are therefore enabled to classify them all into two broad groups, viz., six-rowed barleys, and two-rowed.

To make a further advance in the classification of the different kinds of barley, the shape of the heads of both six- and two-rowed barleys must be taken into account. These may be short and broad, or narrow and long. The long, narrow heads are occasioned by the joints of the rachis from which the corns spring being placed widely apart — in the broad-headed barleys the joints are much closer together (see Fig. 1).

Thus, by grouping barleys in the first place into six-rowed and two-rowed forms by the very simple means of flower arrangement already described, and, secondly, by dividing the six-rowed and two-rowed groups into narrow-eared and broad-eared divisions, we are enabled to place all the different varieties of barley of interest to the brewer in four distinct classes :—

I.

Six-rowed Barley.

Wide-eared, with short joints (*H. hexastichum*).
Narrow-eared, with long joints (*H. vulgare*).

II.

Two-rowed Barley.

Wide-eared, with short joints (*H. zeocriton*, Goldthorpe).
Narrow-eared, with long joints (*H. distichum*, Chevalier).

This classification comprehends all the kinds of barleys which are suitable for malting. There are two uncommon species not employed in malting which do not come under its arrangement, but they may be left out of consideration now.

Having classified all types of malting barley into four main sub-species, Beaven showed how

B. *A.*

FIG. 3.—SIX-ROWED BARLEY.

A. Wide-eared, with short joints (*H. hexastichum*).
B. Narrow-eared, with long joints (*H. vulgare*).

each of these four sub-species may be further divided into numerous varieties recognisable by such characteristics as their colour, the character of the outer skin or husk, the nature

of the basal bristle, and other points of distinction which I need not go into now.

The system of classification just described has been generally accepted in this country, and directly and indirectly it has assisted very materially in advancing our knowledge of malting barley. Another system of classification proposed by Atterberg, a Swede, in 1905, has more recently attracted considerable attention. Like the Körnicke-Beaven system, it possesses the merit of simplicity, and has, perhaps, in certain respects some advantages over the former, but, taken as a whole, these advantages hardly justify the risk of creating complications which are apt to ensue when a well recognised system of classification is replaced by a new one. The main use of any system of classification is

B. A.

FIG. 4.—TWO-ROWED BARLEY.

A. Wide-eared, with short joints (*H. zeocriton*, Goldthorpe).

B. Narrow-eared, with long joints (*H. distichum*, Chevalier).

to assist in indexing and grouping individuals for the purpose of easy recognition, and this appears to be sufficiently well effected by the Körnicke-Beaven system.

The second part of Beaven's valuable paper is devoted to a discussion of certain technical questions of great importance which are associated with the malting value of barley.

The present mode of barley valuation for malting purposes, notwithstanding the advance of scientific knowledge, is still based on the same empirical methods which have been in use for years past. Practically, the whole of the world's supply of malting barley is bought and sold under the rule of empiricism, and scientific method has little or nothing to do with it at present. Now the object of much of Beaven's work has been to trace the connection between the empirical characteristics which are believed to denote malting quality in barley, and their underlying causes ascertained by scientific investigations, and to endeavour to discover if the one is supported by the other. The quality of barley for malting purposes is determined technically by such characteristics as the character of the skin of the grain, its size and shape, its colour, and the relative hardness of its endosperm, together with other characteristics which are comprehended under the term "maturation." How are these characteristics, which are supposed to indicate "quality" of barley from a malting point of view, supported by scientific investigation?

For instance, a thick coarse outer skin, according to empirical testing, characterises poor malting quality in a barley; a thin skin indicates good quality. Why are the contents of the barley corn, in which its malting value lies, correlated with the nature of the skin of the corn? Beaven shows that the energy of every seed-bearing plant, tends in two directions—vegetation, or the actual growth of the individual plant, and seed production, the effort of the plant towards reproduction. These two phases of life are not of necessity equally represented in the same individual plant—in fact it is common knowledge that very luxuriant growth is often detrimental to the free production of flowers and seeds. Now the husk, or thick skin of the barley corn is no part of the true seed, it is merely the withered remains of two leaves of the barley plant which originally enclosed the flower, and which continue to adhere to the true seed when it is ripe. So the husk of the barley corn reflects the character of the vegetative growth of the plant which bore it. What then must we expect of the character of the seed of a coarse and so-called thick-skinned barley? Such a skin is the result of luxuriant vegetation, and Beaven's experiments show that the seed borne by plants of luxuriant growth, induced, maybe, by over-manuring, thin planting, or heavy soil, almost always lacks the quality of good malting barley. It is usually hard, contains excessive amounts of nitrogenous matter, and is deficient in starch. Too luxuriant a growth of the plant does not go with the production of good seed—hence one of the ordinary methods of the valuation of malting

barley by external appearance is upheld by scientific investigation. I may further add that this conclusion has been very amply confirmed more recently by investigations carried out in the Guinness Research Laboratory and described in the *Transactions* of that Laboratory.

The "maturation" of barley as an indication of malting quality is another most important question to which Beaven has devoted a very considerable amount of attention. The quality of maturation, which may be defined as the complete development and ripening of the seed, comprehends almost all the characteristics denoting malting quality in barley, and its importance can hardly be over-exaggerated. In fact, Beaven maintains, with regard to the valuation of barley for malting purposes, that more importance may be assigned to the proper maturation or ripening of the sample than to the particular variety of barley from which the sample has been grown. He does not, of course, overlook the great differences in malting value which exist between the various varieties or species of barley, but considers that even these are less important than maturation, and I am inclined to think that there are very few technologists who will disagree with this view.

The character of maturation is usually judged from the external appearance of the grain. Beaven, however, points out how other data may assist in recording this important quality These data are:—

1. The mellowness of the grain, indicated by its whiteness when cut through.
2. The specific gravity of the grain.
3. The relative starch and nitrogen content of the grain.
4. The character of its nitrogenous matter.

All these data are shown to be interdependent to a greater or less extent. For instance, mellowness or "mealiness" of the grain, that very desirable characteristic for a malting barley, has been shown to be accompanied by air spaces within the starchy mass of the endosperm of the grain; in fact, the white mealy appearance of a mellow corn is occasioned by the presence of numerous small fissures ramifying through this starch-containing part. Consequently a tender grain of barley has a less specific gravity than a steely grain, because it contains numerous air-filled, or possibly vacuous spaces.

Again, steely barley generally possesses a high nitrogenous content, and, being steely, its specific gravity is comparatively high.

High nitrogen content is also intimately associated with the relative amount of starch present in the grain. Barley may contain from 8 to 12, or even more, per cent. of nitrogenous matter, and excess of this matter displaces to a greater or lesser extent the soluble starchy matter of the grain; as a consequence, with a barley of high nitrogenous content there is a loss of extract, for the greater part of the nitrogenous matter which displaces the starch is not capable of yielding available extract.

The relation of the character of the nitrogenous matter of the grain to the data regarding mellowness, specific gravity, and relative starch and nitrogenous content, is less well marked. Beaven shows, however, that by employing 58 per cent. alcohol as a solvent for the barley proteins, certain of the proteins soluble in this solvent are markedly less in amount in steely barleys than in mellow ones, and thus he knits together to some extent the character of the nitrogen constituents of barley with the other characteristics determining maturation.

I regret that it is impossible to refer now, even briefly, to many other important points discussed by Beaven in his attempt to harmonise the more scientific aspect of maturation with that of technical experience. The influence which his work in this direction has exerted in advancing our knowledge of the character of barley suitable for malting purposes is very great indeed.

I must now pass on to consider some of the conclusions arrived at by Beaven when studying certain sub-species and varieties of barley from the agricultural and malting points of view.

The six-rowed barleys, which are so important as malting material, are obtained almost entirely from countries possessing a warmer and more sunny climate than our own and, from the point of view of home agriculture, there is but little to be said at present about them. It is well to bear in mind, however, that experience has shown in recent years that good malting barley of six-rowed type can be grown in this country as a remunerative crop. Some six-rowed barleys are remarkably heavy croppers, and possess characteristics of considerable value. Hybrid six-rowed barleys have been produced which are promising, and marked improvement in the general character of six-rowed barleys has also been obtained by judicious selection. There is, no doubt, a considerable amount of prejudice in this country against six-rowed barley culture, and much of this is well justified; but

it is desirable to bear in mind for the good of both agriculture and brewing that conditions no doubt exist under which the growing of a suitable variety of six-rowed barley may yield very remunerative crops. Such conditions are found both in Belgium and the north of France.

Two-rowed barleys are the special consideration of the agriculturist in this country, and probably will always remain so. As we have seen, there are two distinct classes or sub-species of two-rowed barley in cultivation—the long narrow-eared kind often styled "Chevalier," and the short wide-eared kind, usually called "Goldthorpe" (Fig. 4). Now, about the respective merits of these two kinds of barley very wide differences of opinion exist, more especially with regard to their malting and brewing value.

Thirty-seven years ago, when Dr. Graham lectured, broad-eared barleys were comparatively little grown, but since that time their culture as Goldthorpe, or as hybrids such as Standwell and Invincible, has gradually spread until, in some parts of the country, they appear to be displacing the narrow-eared Chevalier type altogether. Some brewers, who find broad-eared barleys supply material suitable to their need, contemplate this with equanimity; others, probably in the majority, regard the change with great disfavour, for they maintain that the best qualities of beer can only be obtained by the use of malts made from narrow-eared Chevalier barleys. Beaven has much to say in connection with this subject from the point of view of the relative malting value of Goldthorpe and Chevalier barley, but, important as it is to settle the question of malting value, this does not of necessity settle the question from the brewers' point of view—the brewery must be the ultimate court of appeal. Granting for the moment that malts in every respect of equal value, according to our malt standards, can be made from Goldthorpe and Chevalier barley, it does not follow that the results they yield in the brewery will be equally satisfactory. Evidence with regard to this question is very conflicting. Making every allowance for prejudice in one direction and another, practical results indicate that, in some breweries at least, Goldthorpe malts prove inferior to Chevalier for brewing the highest qualities of ale. Very possibly the true cause for a difference of opinion on this question originates in the varying requirements of different breweries. These requirements vary to a very great extent, and may well determine the difference of opinion held on this subject. At present the relative merits of Goldthorpe and Chevalier barley as brewing material remain in dispute, with the weight of evidence tending in favour of Chevalier for the production of the higher qualities of ale.

Apart from the relative brewing qualities of Goldthorpe and Chevalier barley, Beaven's work on their relative malting value is of importance. Goldthorpe barley, contrary to what is often believed, is, according to Beaven, not a more highly nitrogenous barley than Chevalier—in this respect the two barleys are very similar. Neither does Goldthorpe appear to be a less "free-working" barley than Chevalier, when malting conditions are strictly parallel. Its extract-yielding capacity is, on the whole, somewhat larger than Chevalier, and if, in certain respects, it must be placed a little lower than some kinds of Chevalier, on the other hand it is superior to other kinds. In fact, to quote Beaven's own words, his results "prove that sweeping condemnations of Goldthorpe are not warranted," but he also adds, "they prove nothing more." This was the position when Beaven read his paper in 1902, and at the present time there appears to have been no further advance towards a more definite understanding of the subject in this country. It is one that is left for the future to decide, and is certainly one that deserves the special attention of both brewers and agriculturists here, if, as some suppose, there is a prospect of the cultivation of Goldthorpe further displacing that of Chevalier.

There is much need in this country for further knowledge of these and other kindred subjects associated with barley. A good deal has already been done in the direction of hybridising barley and producing new species suitable for malting purposes. Messrs. Garton have been the leaders in this, and Professor Biffen of Cambridge has also taken up the subject, and, following Mendelian methods, appears to be obtaining most valuable results. Beaven is also conducting experiments in the same direction. Experiments have also been carried on at various agricultural centres, notably at the Agricultural station of the University of Leeds, on the influence of different manures on the yield and quality of barley, which have added considerably to our knowledge of these subjects. But no thoroughly systematic investigation of barley both from the agricultural and the malting point of view has

been attempted in this country such as the one which has been carried out by the Danish Department of Agriculture with so much success. No one, of course, looks for assistance from our English Department of Agriculture in any practical investigation of this kind, so it comes with additional pleasure to find that the Irish Department of Agriculture has, during recent years, actively participated in a prolonged and systematic investigation in connection with malting barley, the results of which are of very great interest. As the results of this investigation are but little known in this country, and as they undoubtedly represent the most recent advance in knowledge regarding the cultivation of malting barley, it appears very desirable to refer to them here.* It is true the object of the investigation was to study the requirements of barley cultivation in Ireland, a country where agricultural conditions differ materially from those obtaining here, but nevertheless it will be found that the knowledge gained possesses much interest for us in England.

A few words may perhaps be said with advantage regarding the admirable system adopted in the Irish investigation. The first and main object was to ascertain, in the interest of Irish agriculture, what kind of malting barley was the most profitable for the farmer to grow. Other important points in connection with the influence of manuring on yield and malting quality, time of sowing, climatic conditions during growth and harvesting, etc., also formed part of the investigation, but these points were in a manner subordinate to the main object already mentioned.

The leading experiments, which were commenced in 1901 under the supervision of the Irish Department of Agriculture, were supported very materially by Messrs. Guinness, of Dublin, who not only contributed largely towards the necessary expenses, but also employed the extensive technical and scientific resources they have at their command to assist the investigation. Under these circumstances the experiments were carried on under especially favourable conditions for obtaining valuable practical results.

The experiments were conducted on farms distributed throughout the barley-growing districts of Ireland, and were continued during a period of six successive years. In this way complicating factors associated with soil, district, and varying weather conditions were to a large extent eliminated during the investigations. The various kinds of barley cultivated were grown on two-acre plots, areas sufficiently large, not only to yield thoroughly representative crops for technical valuation, but also quantities of grain large enough to be malted in the experimental malthouse of Messrs. Guinness.

The kinds of barley examined comprised both narrow-eared and broad-eared types. The narrow-eared barleys included the varieties known as Archer, Scotch Chevalier, Hallett's Chevalier, Old Irish and Danish Archer. The broad-eared barleys included Goldthorpe and Standwell, the latter a very well-known hybrid reproducing Goldthorpe characteristics.

The most important object of the investigation was to determine the yield and money value of the different varieties tested. The yield was obtained, after careful supervision during harvesting, by weighing the grain after threshing; from the result, the yield per statute acre was calculated. The money value was determined by multiplying the yield per statute acre by the value of the grain on the Dublin market determined by expert valuation.

The result obtained was styled the "Value per acre."

I will now describe, in as few words as possible, the more important results obtained with the different barleys during the investigation.

Archer.—This variety of narrow-eared barley, which is well known and appreciated in our English eastern counties on account of its high yielding capacity and stiff straw, proved in the Irish experiments to be the most profitable of all the varieties of barley just referred to. The average yield per acre throughout the whole course of experiments was 5 qrs. 25 st., and the value per acre was £8 15*s*. After most careful statistical examination this proved to be 12*s*. more than the nearest competitor in the investigation, and 16*s*. more than the nearest narrow-eared variety. The quality of the barley was generally good, although it was somewhat dull in appearance and less attractive looking than true Chevalier barley; on the other hand it usually proved to be the better material in the malthouse. Somewhat late ripening appeared to be its only drawback throughout the Irish experiments. The somewhat late ripening and dull colour of Archer barley as compared with Chevalier are points well recognised in this country, and are

* For this information I am indebted to a report on "Barley Cultivation in Ireland," printed for private circulation by Messrs. Arthur Guinness, Son & Co.

evidently not peculiar to the Irish cultural conditions.

Scotch Chevalier.—This variety proved to be distinctly inferior to Archer, its "value per acre" being 16*s.* less. The estimated probable error of this comparison is 1*s.* 6*d.*, and the odds that Archer is better than Scotch Chevalier on the farms and during the seasons tested are over a million to one. I may add that I am not responsible for the very sporting manner in which this latter statement is expressed; I quote direct from the Irish report. The "probable error" and "odds" mentioned in this report have been determined by the most approved mathematical means.

Old Irish.—The results obtained with this variety were very poor. Its value per acre as compared with Archer was 22*s.* less.

Hallett's Chevalier.—This variety was even more disappointing than Old Irish, and its value per acre was 29*s.* less than that of Archer.

Danish Archer.—This variety appears to have been derived from a true Archer barley originally imported from our eastern counties into Denmark a number of years ago. It is now very largely cultivated in that country, and is recognised as the best barley grown there. In Ireland this barley proved even better than the ordinary Archer referred to, and its value per acre came out 11*s.* higher.

The broad-eared barleys tested were Goldthorpe and Standwell. Compared the one with the other, the value per acre of Goldthorpe was 16*s.* more than that of Standwell, and the odds that Goldthorpe is a better barley than Standwell are over a hundred thousand to one. In appearance there was apparently little to choose between the two; Goldthorpe, however, proved to be better malting material than Standwell. The smaller yield of Standwell was apparently due to a characteristic it possesses of producing a very considerable number of "deaf" ears. This originates from a general tendency in this hybrid barley of some of the florets to escape fertilisation.

The result of the Irish investigation up to this point proved that Archer (excluding Danish Archer) was the best of the narrow-eared barleys examined, and Goldthorpe the best of the wide-eared varieties. But a careful comparison of the relative merits of these two barleys was very desirable, because there is a general idea in Ireland that wide-eared barleys are more suitable for certain districts and narrow-eared for others. A similar impression exists in this country also, and therefore the results of the Irish investigation in this direction are peculiarly interesting.

Throughout the investigation extending over six years, Archer and Goldthorpe were grown side by side at farms scattered over the whole of the barley-growing districts of Ireland, and in all fifty-one comparisons were made. From a general average of the results obtained, the value per acre of Archer was found to be £8 15*s.* as against £8 3*s.*, the value per acre of Goldthorpe—an advantage of 12*s.* in favour of Archer. The calculated odds that Archer was a more profitable barley than Goldthorpe are about twenty thousand to one. From a general average of all the experiments, therefore, Archer proved to be a better barley from the farmer's point of view than Goldthorpe. Moreover, when the experiments where sub-divided into different districts the same result was obtained, Archer proving to be the better barley in every case.

District.	No. of Tests.	V.P.A. in favour of Archer.	Probable error.	Odds in favour of Archer.
		s. *d.*	*s.* *d.*	
Cork . . .	12	11 0	4 7	10 to 1
Wexford . .	10	10 0	5 0	7 „ 1
Louth . . .	8	15 0	5 7	10 „ 1
Central Plain	21	12 0	3 5	100 „ 1

The conclusion finally arrived at is, that although certain individual soils may still be found which suit Goldthorpe better than Archer, there is no doubt that in the vast majority of cases it will pay the farmer better to grow Archer. This conclusion, of course, applies to Ireland where the experiments were conducted, and where agricultural and climatic conditions are somewhat different from those of this country, but nevertheless there appears to be no *prima facie* reason why future investigation may not demonstrate a similar conclusion here. In this respect alone the Irish experiments are well worth the attention of the agriculturists of this country.

The advantages of purity of seed is another question of great importance which is brought into conspicuous notice by the Irish investigations. During the course of the experiments, it became evident that ordinary, so-called, pure seed of any of the varieties of barley tested, represented a mixture of various strains. Differences of growth and habit, of size of ear,

of time of ripening, and other factors of a minor character, demonstrated the mixed nature of the seed ordinarily cultivated, and evidenced that in any thorough investigation of barley for the purpose of ascertaining the most desirable kinds to cultivate, absolute purity of the seed must be assured. In order to meet this demand, in the first instance pure seed was obtained from a single selected plant or ear of the particular variety under examination, and it was sown under conditions which precluded any chance of accidental admixture. Harvesting and re-sowing were afterwards continued with every precaution to preserve purity, until a crop of pure seed was obtained sufficiently large for cultivation on a farming scale. Subsequently experiments were conducted in which the pure selected seed was grown on a number of farms side by side with the ordinary seed from which the pure strain was originally derived. In all cases the crops grown from selected seed not only exhibited remarkable evenness of growth as compared with those grown from ordinary seed, but the yield at harvest time was also distinctly larger. In the case of Archer, the mean of eleven different experiments demonstrated that the value per acre of the crop from selected seed was 11*s*. more than that of the crop from ordinary seed. Experiments with selected Goldthorpe also showed a somewhat similar gain in value as compared with ordinary Goldthorpe. In fact, the Irish experiments demonstrate to a point of certainty that a great gain may be achieved by proper attention to the selection of pure seed. What this gain would represent for Ireland alone is estimated in the report of the Irish experiments. "If," the report says, "pure selected Archer or Danish Archer were substituted throughout Ireland for the existing varieties, it would result in an increase of yield of six bushels per acre, which would mean an increase in the value of the yield of over £200,000."

There is much more in the valuable report of the Irish experiments on barley culture to which I should like to refer if time allowed, but I must bring my remarks to a conclusion.

I have referred in this lecture to the leading results obtained from the Irish experiments, because, in the first instance they demonstrate the limit of our present knowledge with regard to barley cultivation; and, secondly, because they indicate how much can be done for the good of agriculture by the joint action of the agriculturist and the brewer.

In this country the cultivation of barley still awaits systematic investigation, and every year very many thousands of pounds are lost to agriculture from the lack of knowledge which is undoubtedly attainable. Is it too much to hope that, following the example of Ireland, joint action between the agricultural and the malting and brewing interests may be arranged in order to facilitate a thoroughly systematic investigation of the subject? The prize is a very large one, and, moreover, it is certain of attainment.

No doubt misunderstanding to some extent does exist between the agriculturist and brewer which tends to keep them apart, but, as I have said before, it is based on misconceptions. There is nothing in the economic conditions of brewing which is antagonistic to the welfare of agriculture; on the contrary, the two industries possess many interests in common. Why should not these common interests prevail over misconceptions, and bring agriculture and brewing together for the carrying out of a joint work which would confer great benefit on both industries?

HENEQUEN AND BANANA CULTIVATION IN MEXICO.

The State of Colima is peculiarly adapted for the henequen plant (*agava rigida elongata*), which produces the sisal hemp of commerce. The foot-hills are generally barren of timber, and are often covered with grass, the soil being thin and sometimes rocky, but the climate and all the conditions are perfect for the cultivation of this plant. There is little labour in growing henequen, or in harvesting the crop, and the machinery necessary for the separation of the fibre from the leaves is cheap, and can be worked by the natives. It has been customary in Mexico to cultivate henequen without regard to the number of plants to an acre or to their position. The United States Consul at Manzanillo says that sometimes as many as fifteen hundred are put on an acre of land. The plan usually adopted is to plough and prepare about ten acres of level land, to be used as a nursery, in which the small plants are set six inches apart in rows two feet apart. In this manner, while the larger field is being prepared the young plants acquire a vigorous growth. As the fields are planted, the stock from the nursery is replaced until the first ones set out produce suckers, which may be taken up and left in the sun for two or three weeks, as this makes them better and stronger. Plants in the field are set six feet apart in rows nine feet apart. During the first two years, if the ground is not too rocky, it is planted with maize or beans. After this the henequen requires air and sunshine, and needs no care or cultivation. When the plant commences

to mature (fourth year), the leaves can be cut at any time during the dry season, and every twelve months thereafter. During the first four or five years the plant will produce from fifty to sixty "suckers," which may be used for transplanting. The net profit from the production and sale of sisal fibre is said to be from £20 to £33 per acre. As the henequen plant lives and produces for fifteen or twenty years, without being transplanted, and is not attacked by insects or disease, and requires little expense for harvesting, it possesses a great advantage over crops which have to be planted each year. In many districts of the State of Colima irrigation is not necessary, and banana bulbs may be set out at any time of the year. The native banana (manzana) will not bear transportation for any distance, and for this reason the Governor of Colima appointed a commission to inspect the "Roatán" variety, which is grown in the State of Tabasco. The commission returned with 25,000 bulbs, which were distributed amongst the farmers. The "Roatán" banana is of good size, has a thick skin, fine texture, and is free from fibre and lumps, and has found favour in the American markets. The soil in which the banana is planted should be a sandy loam, and when ploughed and harrowed the ground is measured in squares of three metres (metre = 39·3 inches), which gives about four hundred plants to the acre. When the sprouts reach the height of one foot they may be transplanted. When the land is marked into squares, a hole three feet square and three feet deep is made, the plant being placed in the centre. The reason the bulb is planted at this depth is because of the accumulation of leaves and *débris* which form a fertiliser, and also retain the moisture. The land being set with bananas, may be planted with maize or beans, thus reducing the cost of cultivation the first year. It requires twelve months for a stock to mature and produce a bunch of fruit from the bulb. During the growth of the first stock there will come several shoots, the largest one being allowed to stand, while the others are taken up and replanted. The stock left will attain sufficient growth to produce one bunch of bananas in four months, or three bunches from one plant, or 1,200 bunches per acre annually. Planters receive tenpence per bunch at the plantation, and as the cost of production is £10 per acre, very satisfactory profits are realised. A very fine fibre is extracted from the banana stock, which is used in the manufacture of hammocks.

WOMEN IN JAPANESE INDUSTRIES.

Japan is seriously discussing the advisability of passing laws to regulate labour in its factories, to affect more particularly the hours of labour of women and girls. An interesting statement has been made by the Director of the Industrial Bureau of Japan, which shows how far women are responsible for building up Japanese industries. This report shows that Japanese women's labour as an industrial factor is very great, their influence being keenly felt in almost every industry. Commencing with the production of raw silk, which occupies over 50 per cent. of Japan's total export trade, female labour largely enters into the manufacture of habutar (silk goods), cotton yarn, and other staples of export. The extensive employment of female labour may be due to its comparatively low price, but in many instances work can be done better and more effectively by women than by men. The percentage of women engaged in the industries of Japan is stated to be as follows, as compared with men: Men employed, 34 per cent.; women employed, 66 per cent.; showing that there are nearly twice as many women as men employed. There are usually fixed hours (twelve) as to the time for daily employment. In spinning raw silk, floss silk, cotton, weaving, knitting, and braid manufacture, there were employed, in the latest year for which the figures are available, a total of 373,284 persons classified as follows: Males over 14 years of age, 40,789; under 14 years of age, 2,475; total number of males, 43,264. Females over 14 years of age, 296,424; females under 14 years of age, 33,596; total number of females, 330,020. The wages paid to males over 14 years of age ranged from one shilling, the highest rate, to sevenpence halfpenny. Males under 14 years of age received from fivepence to as little as threepence per day. Females over 14 years of age receive from sevenpence, the highest rate, down to fivepence per day. Females under 14 years of age received from fourpence halfpenny per day down to twopence halfpenny. From this report it will be seen that the wages paid to factory operatives are very small indeed. This fact is also applicable to all other kinds of industrial labour. It is not surprising therefore that Japan's export trade has increased from 13 millions sterling in 1891 to over 46 millions in 1910.

CAMPHOR PRODUCTION IN BURMA.

The camphor tree, principally the *Blumea balsamifera*, seems to be indigenous to certain parts of Burma, and the experiments conducted by the Forest Department to cultivate the *Cinnamomum camphora* show that this tree can be successfully grown in the Upper Chindwin, Myitkyina, and Bhamo districts, as also at Momeik, while in Maymyo the tree is said to flourish. The experiments of the past few years go to show that it can be successfully grown in Upper Burma, and the species is also expected to do well at suitable elevation in the Shan States. There is, therefore, according to the American Consul-General at Calcutta, a fair possibility of a camphor plantation on a large scale in Burma proving successful and profitable, and there is no reason, it is said, why a camphor industry should not be started in the province. The question of camphor distillation in Burma was recently considered by the Forest Department. The first point was to design an

experimental still of sufficient capacity to see if camphor could be manufactured on a commercial scale from the *Blumea balsamifera;* the next point required a chemical investigation to determine the percentage of essential oil in the fresh green plant, and compare it with the percentage obtained from the plant in its dry state. These analytical determinations were made with the plants growing in the Toungoo and Katha forest divisions, and the results show that the branches and leaves of the *Blumea balsamifera* can be profitably distilled for the extraction of the oil and camphor. In North Hsenwi the leaves and thinner twigs are gathered, though mature leaves are preferred, and placed in a bamboo basket, which is put into a large pot containing water, but not touching the water, and on top of the basket a chatby (vessel) of cold water is placed. Fire is then applied. The steam from the water in the large pot passes through the basket, and the cold water on top, which is frequently changed, acts as a condenser. In a few hours the operation is completed, and on the leaves being removed the camphor is found adhering to the sides of the basket. It is then scraped off and placed in bamboo tubes. The yield varies according to the quality and quantity of leaves used in the operation. The camphor finds a ready market locally, as it is largely used as a medicine. The trade is insignificant, as the people extract the camphor only when they have nothing else to do. In Kengtung, on the other hand, a considerable export trade exists with the southern Shan States.

THE RUSSIAN PAPER TRADE.

Russia's paper-mills depend almost entirely on Finland, Germany, and Austria-Hungary for raw material, which dependence is supported by the present preferential tariff in favour of Finland. On account of Finland's proximity to Russian ports of entry, wrapping and wall-paper are carried frequently in ballast. Paper manufacturing has been so long concentrated in the hands of the Finlanders, and the technical features so constantly improved by introducing inventions in machinery and discoveries in chemistry, that paper-making in Russia is also more or less dependent upon Finland. In Finland, according to a recent report of the American Consul at Moscow, 158 factories manufacture paper and paper goods, employing about 15,000 workmen, with an annual output of, approximately, £1,800,000. Forty years ago the paper-making industry in Finland was of little importance. Small beginnings were commencing to show possibilities of future development in the early eighties, and the example of Norway and Sweden did much to stimulate Finland in this direction. In 1885 about 2,000 persons only were employed in the paper and pulp industry. This number had increased in 1895 to 4,000, and in 1905 to 11,000. It is estimated that now 15,000 people are working at the factories and mills. Finland and Russia combined furnish only about 3½ per cent. of the total amount of paper produced in Europe, yet on account of immense extents of forests, accessibility to the ocean and numerous waterfalls, the former is certain to play a most important part in the world's future market. The paper industry is carried on extensively at many important commercial centres in Russia, including the provinces of Moscow, St. Petersburg, Novgorod, Livonia, Vladimir, and Kaluga. It also prospers in the governments of Perm, Vologda, Kiev, Vilna, Tula, Viatka, Kostroma, and Vitebsk. Six factories produce mechanical wood-pulp; five manufacture sulphite-pulp, and three specialise in cellulose products. The majority of mills manufacture "boards" and "wrappings." About fifty concerns produce cardboard, and the same number wrapping papers. In newspapers, only seven mills are working for Russian requirements, though there is a disposition to increase the number so as to supply the entire trade of the country, which is in the hands of the Finns. Formerly all cigarette paper was imported, but recently Russians have undertaken to supply themselves, as the demands are incredibly large. They appear to be succeeding in the manufacture of this kind of paper and its subsequent fabrication into tubes, which are supplied with a cardboard mouthpiece. A simple machine was invented some years ago by a Russian for filling the tubes with tobacco, of which one pound will suffice for 1,000. Many factories found in the country are provided with machinery of the latest type and run by electric motors, while many are content with old-fashioned equipments. Competition in paper-making is keen, but various firms in Moscow report that profits under favourable conditions are high, reaching sometimes 60 per cent. This applies especially to the production of cellulose, both bleached and unbleached, of which Finland appears to have the advantage in the means of manufacture. Russians have attempted at several places to compete, but they failed because their products were inferior to the imported ones, and the cost of production was almost prohibitive. Russia manufactures every quality and design of paper, but local dealers state that, as a rule, products are inferior, excepting news paper, which is claimed to be superior to that manufactured in Germany and Austria, the texture being firmer and the gloss more pronounced.

HOME INDUSTRIES.

The Railway Strike.—The railway strike of last week was by far the most serious that has occurred in our railway history. Happily it had lasted only two days when a truce was arranged by the acceptance of the Government proposal to investigate the working of the Conciliation Agreement, and to report what amendments, if any, are desirable in the scheme, with a view to the prompt and satisfactory settlement of differences. It is thought by some that, but for the misunderstanding of the Prime Minister's first offer of a Royal Commission,

this solution would have been accepted on the 17th inst., and a strike averted. Later in the day Mr. Lloyd George more fully explained the proposal, namely, a small Commission of five, two representatives of the employers, and two of the workmen, with a neutral as chairman, to inquire into the working of the Conciliation Agreement, to sit continuously, and to report without delay, the assurance being added that, if necessary, Parliament shall deal with the recommendations forthwith. Unfortunately this elucidation came too late to prevent the strike, but fortunately for all concerned the arrangement foreshadowed was accepted late on Saturday night, and the men were to resume work as soon as possible, none being punished for the part they played in the recent disturbances. There can be little doubt that there is substance in some of the complaints of the men, and nothing is to be gained, and much may be lost, by treating, as some leading newspapers have done, the demands of the men as midsummer madness, probably due in large part to the abnormal heat. The first complaint of the men is that they cannot get their grievances properly sifted. In 1907, when the Conciliation Boards were formed, it was pointed out that the exclusion of trade union officials from representation upon the Boards would breed trouble. There is no great industry in the country, other than the railway industry, where the wage conditions do not come before joint boards consisting of representatives of employers' associations and of trade unions, and these joint boards have been of great assistance in settling disputes in a peaceable and friendly manner. The railway companies defend their refusal to admit trade union officials to the Conciliation Boards on the ground that less than one-fourth of the railway men belong to trade unions. But there is one exception to this general refusal of the railway companies. The North-Eastern has negotiated with trade union officials for many years, although not recognising them as representing the whole of the employees, and the arrangement has worked advantageously to all concerned. Without trade union officials—always a moderating force in these days—to represent them, the men are not strong enough to enforce the most reasonable claim. Again, new and more scientific methods of operating the traffic have compelled the men to work more strenuously, so that, even where the rate of wages is slightly higher than it was, in proportion to the effective work performed it is less. And this at a time when the cost of living has increased, and is increasing. Under present conditions the public, especially in the passenger service, are better served by railways, and shareholders are beginning to get a somewhat better return upon their capital, though even now it is only about 4 per cent.; but the position of the men has not improved. Nor is it likely to improve until the directors call to their assistance the trade unions, whose special task is to secure fair treatment for the operatives, to obtain for them a fair rate of wage, having regard to the rising cost of living, and standard of comfort. In urging this view of a great and complicated question, no support is given to the action of the men in issuing what may be called their twenty-four hour ultimatum—an action calculated to alienate the sympathy of their best friends.

Electric Traction.—A writer in the *Times* (August 14th) asks why it is that electric traction in this country does not pay those who find the capital for working it? It is not a sufficient answer to say that in years gone by there was extraordinary difficulty in obtaining power to construct, and afterwards over-regulation, which greatly increased both the first cost and working expenses. England should be the most eligible country in the world for electric-traction schemes, yet, judged by the standard of comparable industrial securities, the average return on the many millions invested by municipalities and companies in urban, suburban, and inter-urban transit is painfully insufficient. The writer in the *Times* finds the solution of the puzzle in the small fares charged. The price of travelling is too low, and it is solely because of under-payment by the passengers that practically the whole list of electric traction undertakings in this country consists of insufficiently remunerative systems—from tube railways down to small tramways and light railways. It is not a popular view, but there is much to be said for it. In the period of horse tramways — about 1878 — the average receipts per tramway passenger were 1·84*d.*; in 1898, when there were numerous steam lines, it was 1·23*d.*; in 1910, with almost universal electric working, it was only 1·09*d.* Meantime labour conditions have become more onerous, and constructional maintenance and renewals more costly.

Imports of Corn.—In the volume of agricultural statistics just issued by the Board of Agriculture and Fisheries the figures relating to the imports of corn in 1910 are given. From these it appears that the importation of wheat was the largest on record, exceeding the previous highest, that of 1904, by 826,000 cwts. Flour imports continue to decline, being just under 10 million cwts., or 1,092,000 cwts. less than in 1909. The feature of the year's importation of grain was the unprecedented receipt of 28,942,000 cwts. from Russia. This total was over 11,000,000 cwts. (62 per cent.) greater than in 1909, and nearly 3,400,000 cwts. more than the previous highest importation from Russia, that of 1905. Record consignments were also received from Australia, the total of 13,117,000 cwts. being 3,417,000 cwts. more than in the previous year. The contribution from Canada was slightly less than in 1909, but otherwise had not been previously exceeded. On the other hand, Argentina, Chili, and the United States supplied nearly 10½ million cwts. (28 per cent.) less than in 1909. Supplies from the British Empire overseas formed in 1910 a higher proportion (35·2 per cent.) of the total than in any of the six preceding years.

Wool.—The total quantity of sheep, lamb, and alpaca wool imported in 1910 was 803,000,000 lbs., or only 5,000,000 lbs. less than in the previous year, when the imports were the highest on record. Re-exports amounted to 335,000,000 lbs., leaving 468,000,000 lbs. as the net amount retained for consumption, an increase of 50,000,000 lbs. over the net imports of 1909, and of 17,000,000 lbs. over the net imports of 1907. The year 1910 therefore created a new record in this respect. The proportion of total imports from British possessions was 83 per cent., about the same as the previous year. The supplies from South Africa and India were somewhat smaller, but Australia and New Zealand shipped larger quantities, the latter country thus surpassing the record only made in 1909. Most European countries sent smaller supplies, but France and Germany were exceptions. Imports from Argentina and Uruguay fell from 47 million to 36 million lbs., but those from other parts of South America increased.

The Crystal Palace.—The Crystal Palace, with all it owns, theatre, concert-room, picture galleries, park and gardens, statuary and casts, books and curios, premises covering ground-rents amounting to nearly £1,500 per annum, is in a few weeks to be offered in one lot, as a going concern, at public auction. Meantime there is a movement on foot to raise a million sterling by public subscription for its purchase as a memorial to King Edward, and another project will form the subject of discussion at a meeting shortly to be held at the Mansion House, under the presidency of the Lord Mayor. It may be doubted whether the Palace can be saved for public purposes unless with the help of Parliament, and that would not be easy to get. The financial record of the Crystal Palace has been consistently disastrous. Opened in 1854, much was expected of it, and of the public support it would win, but it soon got into serious financial difficulties, the shareholders received no dividends, and as far back as 1887 the Company defaulted in payment of debenture interest. Reconstructed, it defaulted on its second debentures in 1891. Fresh working capital was introduced, but with no success. Before the Receiver was appointed early in 1909 the outstanding debentures stood at £500,000, and the ordinary capital had become a negligible quantity. At last the debenture-holders are seeking to enforce an absolute sale.

The American Cotton Crop.—At the end of last week the Liverpool quotation for American cotton was 6·66*d*. per lb., as against 8·07*d*. per lb. a year ago, and 6·69*d*. per lb. in 1909. As late as May last the grade now quoted at 6·66*d*. was quoted at 8·42*d*. per lb. The main cause of the drop is of course the continuance of brilliant weather conditions in the American cotton belt. The present expectation is that the growing American cotton crop will be the largest yet grown, and will come to port early enough to dissipate the pinch which has seemed almost certain to mark the finish of the present season. The estimate of crop conditions published by the Washington Agricultural Bureau at the beginning of the month, placed it at 89·1 per cent. (100 being theoretical perfection) in comparison with 88·2 a month earlier, 75·5 per cent. this time last year, and 71·9 per cent. this time two years ago. The total crop of 1908 was 13,829,000 bales; of 1909, 10,651,000 bales; of 1910, about 11,800,000 bales; but whereas the estimated acreage in 1908 was only 33,370, this year it is 35,004 acres. The visible supply at July 28th was in 1909, 2,145,000 bales; in 1910, 1,331,000 bales; in 1911, 1,313,000 bales. The outlook at the moment is unexpectedly favourable, but it is well to remember that the most critical months are still to come. It must not be forgotten, too, that the sanguine estimates of the Egyptian crop, current some time ago, have been greatly modified by reports as to the ravages of worms, and anything that hurts the Egyptian cotton crop affects Lancashire in a peculiar degree, since the fine counts are made very largely out of Egyptian cotton.

Soya Beans.—A Yellow Book published by the Chinese Imperial Maritime Customs, and dealing with the subject of developments in Manchuria, refers in the following terms to the Soya bean:—"The Changchun-Kirin railway, now under construction, will in a couple of years open the way to the development of the Sungari region to its fullest capacity, and if this line is continued to the Korean frontier new districts will be thrown open, while the Chinchow-Aigun line, or at least a portion of it, would, if constructed, traverse a country where beans might thrive. The eager competition to secure beans in Europe shows no signs of slackening; and the North American continent appears to be about to enter the field as a consumer, for a large shipment of beancake has just been sent to Seattle, and there appears to be a very good opening for the product on the Pacific coast, where the heavy railway freights from the East have caused dairymen and feeders to look round for a cheaper feed than that which comes across the Rockies. With freight from Darien to Seattle at only (gold) $4 per ton, a good market should be developed. Soya beans are being grown in British West Africa, and experimental planting is carried on in practically every British colony; but it seems doubtful whether such experiments can meet with success in competition with the Manchurian product, which is raised under ideal climatic conditions and by the cheapest possible labour. The general impression prevailing seems to be, therefore, that the bean trade has a good future before it; that the time of stress through which it is passing will not last much longer, and that business will settle down when once normal conditions have been restored."

The Railway Dividends.—Increased traffic, due to more active trade and industry, and greater economy in working, have produced very satis-

factory results for the first six months of the present year from the dividend point of view, notwithstanding increase in working expenses. For this increase is 1 per cent. less than the rate at which the gross receipts improved, showing that the working cost was smaller. The proportion of expenditure to gross revenue was only 63·7 per cent., against 64·3 per cent. for the corresponding half of 1910. With only two exceptions — the Great Northern and London and South-Western, which show no change—all the great companies have increased their rate of distribution, and all but two have carried forward more than a year ago. The Midland dividend is ¾ per cent. more than for the first six months of 1910, and the London, Chatham and Dover is able to pay the full amount due for the half year on the Four and a Half Per Cent. Arbitration Preference against only 3 per cent. Every other company paying dividends on its ordinary stock has increased its rate of distribution by ½ per cent., with the exception of the two companies named above.

CORRESPONDENCE.

CANTOR LECTURES ON "ETCHING."

When anybody with some knowledge of an intricate subject, treats that subject before audiences in a couple of lectures intended to be as little dull as may be, and spreading perhaps germs of knowledge, there is generally somebody who thinks it "only right" to point out that another treatment of the subject than that adopted deliberately is at least possible. This singularly obvious fact is really all that Mr. J. Pennell, stirred by a holy wroth, has conveyed to us in his scheme for lectures on ' Etching" so preferable to mine, except, indeed, his wish to be disagreeable to me—which might have been taken for granted.

My claim for attention to Bega's etchings—much less lengthy, by the by, than Mr. Pennell angrily states—is inadmissible, it appears, only because Mr. Pennell is "blankly ignorant" of them. Much else would be inadmissible on such a reason assigned.

Those living Etchers whom I praise, and whom Mr. Pennell does not approve of, he prudently avoids particularising. To Mr. Pennell—a one-sided person who, with one idea to occupy his head, finds that head much too full to entertain any second or third—it cannot, of course, occur that had I spoken at length of Vandyke or Piranesi, much about others must have been omitted that certainly needed saying. If, indeed, I left out Turner, that was because his etchings were only intended to be brilliant preparations. Even Mr. Pennell probably knows that my books contain tributes to him. Sir Charles Holroyd and Mr. Spence—Mr. Pennell's new-born enthusiasm for whom I heartily welcome—were mentioned in the lectures if not in the report. I have for years made their eulogy. As for the Belgian, Rops, I am content to leave to Mr. Pennell the monopoly of enjoyment of Rops' singularly uninteresting indecencies.

But why continue, since Mr. Pennell's whole complaint is based on the delusion that it is the business of a couple of lectures to contain all the material of an exhaustive treatise? Let him "wait and see"—in the later autumn—my largest and, I suppose, final volume on the subject of which he would wish us to think I know so much less than he does. But then, again, one has to remember that it is possible to "wait" and still not to "see."

A parting shot! I am, it seems, no authority on Etching. And that is doubtless why, when Mr. Pennell's own prints were issued and exhibited in his own land, two or three years ago, his publishers, as Mr. Pennell knows well, thought it particularly worth while to invite me to write, for the American public, an introductory word about them.

Peace be with him! FREDERICK WEDMORE.

NOTES ON BOOKS.

REGIMEN SANITATIS: THE RULE OF HEALTH. From the "Vade Mecum" of the Famous MacBeaths, Physicians to the Lords of the Isles and the Kings of Scotland for several centuries. By H. Cameron Gillies, M.D. Dedicated to the Marquis of Bute. University Press, Glasgow: Robert Maclehose & Co., Ltd. 1911.

Here is a book that, within its class, outwings all commendation. It is the fourth of a series entitled "The John Ryland Facsimiles," consisting of the reproduction in facsimile of old printed books and MSS. in the possession of the Governors of the John Ryland's Library, Manchester. The first volume of the series, reproduced in 1909, with an Introduction by Mr. Henry Guppy, was "The Propositio" of John Russell, printed by Caxton, *circa* 1476; the second, reproduced in 1910, with an Introduction by Mr. Henry E. Newberry, and a Vocabulary by C. Wyld, was "A Booke in Englysh Metre, of the Great Merchauntman called 'Dives Pragmaticus,'" printed by Alexander Lacy, *circa* 1563; and the third, reproduced in 1910, with an Introduction by Mr. Guthrie Vine, M.A., "A litil Boke for the Pestilence" ["Black Death"], printed by John Lettou, *circa* 1485. The first and third are mere tracts, far more interesting on account of their printers than their contents, and owe their preservation to having been printed, and bound; for once printed and bound, "A book's a book—although there's nothing in 't." The second is most interesting, as giving in about 112 prefatory rhymed lines and 74 rhymed quatrains, a complete list of the craftsmen and merchants' wares that made up the daily traffics of the home and foreign trade of the period. The titlepage

refers the reader rather widely to "Deut. 23" and "Levit. 19," the reference undoubtedly being to Levit. xix. 35-6: "Ye shall do no unrighteousness in . . . meteyard, in weight, or in measure. Just balances, just weights, a just ephah [for dry goods], and a just hin [for liquid] shall ye have." The book would have delighted Sir Henry Yule, the greatest of English exponents of the mediæval commerce of the historical Old World. But this fourth volume of "The John Ryland Facsimiles" far surpasses the rest of the series in the fourfold praises due to it, for its intrinsic attractiveness, its scientific value, the scholarly translation by Dr. Cameron Gillies of its text from the original Gaelic, and his learned notes in exposition of it. As edited by Dr. Gillies, the volume is a most inspiring guide through the tangled history of the evolution of mediæval medicine in Scotland, and, indeed, Great Britain; and in its lesser degree proves, as was once and for all proved by Sir Henry Yule's "Marco Polo" and his glorious "Glossary" [Hobson Jobson], that in the hands of the predestined man, books on the driest and least considered subjects, became veritable "talismans and spells."

The true form of the name MacBeath is Machbeathadh, meaning "Son of Light," and from the eleventh century it has been a "kenspickle" name in its numerous widely-varying forms of McBetha, McgBeth, Bead, Beda, Betune, Beatoun, Biotun, Peudan, Peden, etc., in north-western Scotland; while Bethune in eastern Scotland [Fife] may be another form of the name. The MS. of the MacBeath's *Regimen Sanitatis*, was "discovered" by Dr. Gillies himself in the British Museum; and his Introduction to the volume before us traces it through some of its wanderings during the past three hundred years, until it found its safe, if for a while cryptic, refuge in the Museum. It may be identified as the "Vade Mecum" of John MacBeath, who lived about the middle of the sixteenth century; and is probably based on similar note-books that had been transmitted, with ever-increasing additions, from generation to generation in this family of famous Scottish physicians. Apart from the accumulation of experience in the practise of their profession, the MacBeaths' knowledge of medicine by reading seems to have included all the best available in their time. Martin, "Gent," who travelled in the north-west of Scotland in 1700, states that "Fergus Beaton in South Uist possessed the following MSS., namely, Avicenna, Averroes, Joannes de Vigo [Surgeon to Pope Julius II.], Bernardus Gordonus [author of *Lilium Medicinæ*], and several volumes of Hippocrates"; and Dr. Gillies adds: "John [MacBeath] might have sat for his portrait to Chaucer as his 'Doctour of Phisik':

Wel knewe he the olde Esculapius,
And Deiscorides, and eke Rufus,
Olde Ypocras, Haly, and Galien,
Serapion, Razis, and Avycen,
Averrois, Damascien, and Constantyn,
Bernard, and Gatesden, and Gilbertyn."

The stimulus given to the intellect of Greece, the vitalising intellect of the whole civilised world to the present day, by the emotional and spiritualising East, through the invasions of Darius and Xerxes, powerfully reacted on the East through the conquests of Alexander: centuries after which the now Hellenised East once again reacted on the West, through the propagation of Christianity and the conquests of the Saracens; who in this way served to uphold over western Asia, and northern Africa, and southern Europe, during the darker centuries between the fall of Rome and the fall of Constantinople, the ever-revivifying, reinvigorating, and reanimating traditions of Greek science and philosophy, learning and literature, and art; for Saracenic art also was but a recrudescence of Greek art applied to the uses of the Saracens, and the new world of Islam created by them. Of the schools of the New Learning, revived or founded in the wake of the Saracens, the three that became most famous were those of Monte Casino, originally founded by St. Benedict himself, A.D. 529, on the site, it is said [as said also of our St. Paul's], of a temple of Apollo, to which a medical school was now added; the greatest teacher wherein was Constantius Africanus [Chaucer's Constantyn] of Carthage [1018–87], a great Arabist, "Orientis et Occidentis Doctor," and translator of Hali's *Compendium*, under the title of *Pantegni*. The others, Salerno and Montpellier, were more especially medical schools. The School of Salernum, nicknamed "Civitas Hippocratica," was founded A.D. 1150, and its two notable works of permanent value, not only to the student of the history of medicine, but the medical practitioner, are the rhymed *Regimen Sanitatis Salerni*, and the *Compendium Salernitatum*. The former was addressed to Robert, son of William the Conqueror, "Anglorum Regi" [who was cured of a wound at Salerno A.D. 1101]; and it at once became, and for centuries remained, the "Vade Mecum" of every medical student and physician in civilised Europe:—I fancy because once read you never can forget the slow and steady tread, and sure and sober lilt of its admirable monkish Latin lines. When I was a student at Edinburgh, 1848–54, copies of the *Regimen* were still turning up at one and another of the sales of second-hand books there; and I possess five different editions of the book bought by me during those years. Montpellier was, like Edinburgh, a university [its sexcentenary was celebrated in 1890], wherein the teaching of medicine was the greatest feature; and it was there that Bernardus Gordon, of the *Lilium Medicinæ*, taught; and that other Scot named by Chaucer, John of Gaddesden, and Gilbert ["Gilbertyn"], "the Englishman," author of the *Laurea Anglica*, and a *Compendium Medicinæ*, were taught. The MacBeath "Regimen Sanitatis" is based, as Dr. Cameron Gillies well expresses it, in form, on Gaddesden's *Compendium*, and in substance, on the *Regimen Sanitatis Salerni*.

Turning to the text of the volume, what is most remarkable about it is the constant insistence,

implicit or explicit, of that counsel of perfection in all sane medicine,—prevention is better than cure:

"Principiis obsta: sero medicina paratur
Cum mala per longas convaluere moras;"

but enforced, not in the spirt of Ovid [Remed: Amor: 91–2], but of Thomas à Kempis in his reference to these lines in the "De Imitatione Christi" [I., 13, Hirsche 1891]. The Third Chapter, dealing with diet, is so simple in its prescriptions, and so pious in spirit, that it might have been written by a native Hindu "medicine man," who still follows the precepts of the Greek and Roman art of healing as received by him direct from his Aryan forefathers, or, at latest, through the intermediation of the Arabian writers on medicine. Stretch yourself well on awakening; bathe, and clean your teeth, not with a hard tooth-brush, but with the leaf of a melon or the skin of an apple. Then, with cleansed lips, say your "Hail Marys," etc. Next take a moderate walk; and on getting hungry take your food, and do not be too long before appeasing your appetite. Eat simply, and of one dish, and not too much of that. Food should not be taken more than twice a day, and indeed it would seem that once in sixteen hours was considered enough. The second daily meal, supper, should be light and short, sleeping on a full stomach being in every way injurious, more especially to the eyesight. Never bathe on a full stomach. Fat, or rich food, may be taken in winter, but should be avoided in summer. Milk should never be taken with fish [as it was thought to produce leprosy, a belief still held in India]. Sleep should be taken at night, not during the day; or if in the heat of noonday, let it be very brief. Never eat on a troubled mind. Such, in *précis*, is the MacBeaths' "regiment of eating and drinking:" and could anything be more sensible, or closer to the dietary regulations enjoined by the *vyds* and *hakims* of India, whether of the *Yonani* [Ionian], or "Greek" school, so called, or the *Misri*, or "Egyptian" [called also *Suryani*, *i.e.*, "Syrian"]: the Yonani traditions coming down from Hippocrates; he having derived them from the Egyptians, Persians and Hindus, going back possibly to the *Ayur Veda* section of the *Atharva Veda* of the Aryan invaders of archaic India.

I have said enough to demonstrate the deep and diversified attractions of the volume, and to justify my praises of it; and of its erudite and brilliant translator and editor. But I must add yet further expressions of gratitude to its printer and publishers. In paper, typography, "forwarding," it is perfect; and, whether accidentally or intentionally, most happy in its binding. Dr. Cameron Gillies knows how to quote from Chaucer, and either he, or his publishers, would seem, when considering the binding of this volume, to have had in mind Chaucer's lines on "A Clerk of Oxenforde"—

"For him was lever han at his beddes hed,
A twenty bokes, clothed in black or red."

When Chaucer wrote this he had in view the current colours of the cloth-wrapt books of his day, black, red, and blue, which continued to be the prevailing colours of bookbindings so long as cloths of various denominations were used in Europe for the purpose [v. National Gallery], as they are still used, in envelope form, for MSS. in India. The whole aspect of the binding of Dr. Cameron Gillies' volume is of the fifteenth and sixteenth centuries bound books, and this superadds to its other merits the talismanic touch, that after all is, in our heart of heart, the compelling spell of the rare books that in every detail set forth the good faith of everyone, author, printer, "reader," illustrator, paper-maker, binder, and publisher, concerned in their production.

GEORGE BIRDWOOD.

CACAO. By John Hinchley Hart, F.L.S. London: Duckworth & Co. 7*s.* 6*d.* net.

The late Mr. J. H. Hart—for he has, unfortunately, died since the completion of the work under notice—was well known as an authority on tropical agriculture and botany. He was superintendent of King's House gardens and grounds in Jamaica during their formation in 1875; superintendent of the Government cinchona plantations in 1881; agricultural director of the public gardens and plantations in 1886; chief of the botanical department in Trinidad in 1887, and for many years superintendent of the Royal Botanic Gardens in Trinidad. He also wrote various books and reports on cacao, forest conservation, and pamphlets on the cultivation of West Indian products, and he was responsible for introducing many of the existing varieties of cacao into Trinidad. His knowledge of his subject was, therefore, both theoretical and practical, and in the present volume he has given us a very complete and valuable manual on the cultivation and curing of cacao. Starting with a chapter on botany and nomenclature, he proceeds to deal with the question of selection of land, nurseries, planting of cacao, manuring, pruning, diseases and pests, and picking and harvesting; he then describes at length the operations for drying, etc., and the apparatus required therefor, and discusses generally the management of a cacao estate. The remarkable increase in the export of Trinidad cacao is doubtless due in no small measure to Mr. Hart. In 1891 the quantity exported was 16,188,493 lbs., valued at £439,786; this rose steadily till in 1908-9 the figures were 49,137,088 lbs., valued at £1,152,285. The world's production of cacao for the year 1910 is estimated at 478,800,000 lbs. Ecuador comes first, with 84,600,000 lbs.; San Thomé second, with 80,500,000 lbs.; and Trinidad third, with 67,500,000. Of British colonies (with a grand total of 138,500,000 lbs.), Trinidad is easily first, British West Africa ranking second with 55,200,000 lbs.

These figures will be sufficient to indicate the great extent of the cacao industry, and certainly every one interested in it would do well to study Mr. Hart's volume.

GENERAL NOTES.

The Study of Pellagra. — The second field commission for the investigation of pellagra has just left London for the Continent. It is composed of Dr. Louis Sambon, Lecturer at the London School of Tropical Medicine and Parasitologist to the Wellcome Physiological Research Laboratories, and Dr. Albert T. Chalmers, Lecturer on Pathology and Animal Parasitology, Ceylon Medical College. These two members of the Commission will be joined by Professor Haase, of Memphis, U.S.A., Dr. Cole, of Atalanta, U.S.A., and Dr. Martinez, of Yucatan, Mexico. The commission will proceed to the study of the epidemiology and etiology of pellagra in Hungary, the Austrian Tyrol, Spain, and the south of France. The Governments of Austria-Hungary and of Spain have shown great interest in the work of the Commission, and have granted every facility for the prosecution of the study they have in hand. Mr. H. S. Wellcome, so well known for the many services he has rendered for the advance of scientific medicine, especially of tropical medicine, and himself a member of the Pellagra Investigation Committee, has defrayed all the expenses of the present field commission. The work in Italy in the spring of 1910 by Dr. Louis Sambon, has gained so many converts to the belief that pellagra is not due to eating damaged maize, but to a parasitic disease conveyed by the bite of a fly, that Mr. Wellcome's timely help will enable Dr. Sambon and his colleagues still further to investigate a disease which causes widespread misery and fills the lunatic asylums in every region where it prevails.

Fire Precautions at the Coronation.—The British Fire Prevention Committee have published a report on the precautions taken to prevent fires during the Coronation celebrations. Some 14,000 bills were posted warning the public of the danger of carelessness in respect to smoking, matches, and the use of highly inflammable material such as muslin, voile, flannelette and celluloid articles; about as many slips and letters were sent to occupiers on the route of the procession and others, dealing mainly with the dangers of decorative materials, safeguards as to stands, illuminations, etc., and about four hundred newspapers and journals were induced to draw attention to the subject. Special preparations were made by the London Fire Brigade to ensure the safety of the Abbey. In various parts of the building there are thirty-one high-pressure hydrants, and the south-east tower contains a large water-tank with a capacity of 60,000 gallons. Direct telephonic communication is provided to the Westminster fire-station in Francis-street, a motor pump with crew was located outside the annexe, and during Coronation day picked firemen were placed at fixed points throughout the Abbey, each with an electric fire alarm in readiness to communicate with a general switchboard on ground level, from which a call could be instantly given to the firemen in waiting outside the building. It was no doubt owing largely to the action of the Committee that accidents were so few. On June 22nd only one fire occurred in a building on the Coronation route, and this was probably due to defective cooking apparatus. Only eight fires, attributable to the celebrations and illuminations, occurred in the evening. On June 23rd there was only one fire near the long route of the Royal progress, and two in the evening.

Public Works in Morocco.—Notwithstanding the disturbed state of the country, some little progress is being made in Morocco in the direction of public works. In his report on the trade of Morocco just issued, Mr. Consul-General White (Annual Series No. 4624) says that tenders have been invited for the construction of five sections of roads, and of additional buildings at the Tangier Customs House. Land telegraph wires are being placed to connect the existing wires from Casablanca with Rabat to the north and with Mazagan to the south, and the wireless telegraph apparatus at Rabat will be transferred to Saffi, so that all the western ports, except Laraiche, will be in telegraphic communication with Tangier and with the rest of the world. This will be a great boon to merchants. More important public works are in contemplation, but it is not yet known when tenders will be invited. The first to be taken up will probably be, says the Consul-General, (1) the erection of lighthouses and harbour lights, and placing of buoys where required on the coast; (2) Tangier waterworks; (3) harbour works at Tangier and Casablanca. There will also be further road construction and other minor works. The competition for the trade of Morocco continues to increase. As the ports are improved, and roads and bridges, and eventually railways in the interior are made, the trade of the country will be very largely increased. British merchants and manufacturers should, therefore, do all in their power to increase their hold on the market. British trade still maintains its position at the head of the list, notwithstanding the great addition to the French total by the trade across the Algerian frontier, which is classed as entirely French, though doubtless some of the goods are of British or other origin.

Tomato-Seed Oil.—The manufacture of an oil from tomato seed is an industry of quite recent date in Italy, where the growing and preserving of tomatoes is carried on extensively in many parts of the country. In the province of Parma alone, upwards of 84,000 tons of this fruit are packed every season. The utilisation of the seed, which forms so large a percentage of the waste in the process of packing, and which was formerly thrown away, must now add considerably to the profits of the packer. This oil somewhat resembles that of cotton seed in its properties, and it is beginning to be in steady demand for soap-making.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

BREWING AND MODERN SCIENCE.

By Professor ADRIAN J. BROWN, F.R.S.

Lecture II.—Delivered February 13th, 1911.

MALTING.

In my previous lecture I explained the position in which we now stand with regard to our knowledge of malting barley, and indicated the direction and manner in which further knowledge of great value might be obtained. This evening I propose to describe the position of scientific knowledge with regard to certain questions connected with the technical operations of malting.

In every operation of the maltster and the brewer we are brought face to face with biological problems of great complexity, but in none is this more conspicuously evidenced than in malting. The brewer has to obtain his sweet wort, a complex fermentable solution of organic matter mainly of carbo-hydrate and protein nature, from the hard contents of the barley corn of which only a very small portion is naturally soluble. In order to do so, empirical knowledge dating, probably, from pre-historic times, teaches that he must first make the seed germinate or commence to grow, and that the changes which then take place will enable him to accomplish his object. What are these remarkable changes which take place in the seed during germination, and how do they come about? To obtain an answer to these questions we have to investigate a most interesting problem of vegetable physiology, and one which, like all problems associated with life, appears to become more complex the further we push our investigations.

I propose to describe the progress of our knowledge relating to this problem of the germinating barley corn, and attempt to bring such knowledge up to date; before doing so, however, it appears desirable to say a few words about the nature and constitution of the barley corn. I hesitate to touch on so well worn a subject here, but I think a few minutes devoted to it now will materially assist my future remarks.

The barley plant is a monocotyledon belonging to the family of the Gramineæ or Grasses,

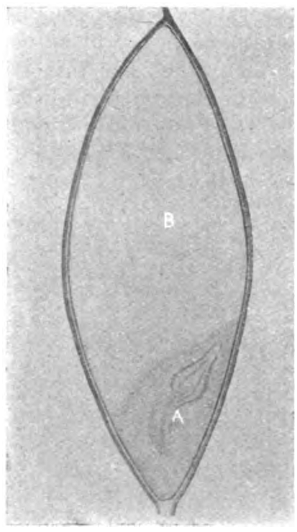

FIG. 5.—LONGITUDINAL SECTION OF A BARLEY CORN.

A. The embryo, or germ.
B. The endosperm, or starch-containing portion of the corn.

and its seed, typical of the seeds of all grasses, is constructed in a somewhat exceptional manner. A longitudinal section of a barley corn (Fig. 5) illustrates this. It will be seen that the germ or embryo of the seed occupies comparatively a small space at the lower end of the grain, and that the remainder of the space within the covering of the grain is occupied by the endosperm or starch-containing part of the seed. The latter part of the seed constitutes the food

reserve for the young germ, to be used in the early stages of its growth before it is sufficiently developed to live the life of a fully-developed plant. The seeds of all plants contain reserve material accumulated for this purpose, but the manner in which the reserve material is stored in the grass seed, and the way in which it is used, is exceptional. The food reserve of most seeds is stored within living tissue, or is otherwise directly associated with the germ, and its absorption during the growth of the young plant is the result of physiological processes of a so-called intracellular nature. But in the grass seed the food reserve has no direct connection with the germ, and is utilised by the germ through the agency of special physiological processes which are all important for the maltster. Fig. 5 illustrates the arrangement of the embryo and the endosperm of a barley corn. In the more highly-magnified representation of the germ end of a corn (Fig. 6), the germ and the endosperm adjoining it are shown more clearly. It will be noticed that they touch each other, but that there is no appearance of direct connection—in fact, the two parts can be easily separated without injury to either. The young plant, constituting the growing portion of the embryo, represented conspicuously by its plumule and radicle, may be seen lying within a mass of cells composing the rest of the embryo. When germination commences the plumule develops into the stem and leaves of the growing plant, and the radicle develops into its roots; but the portion of the embryo lying immediately in contact with the endosperm, which is called the scutellum, retains its position until the contents of the endosperm have been absorbed as food for the growing young plant; in fact the scutellum acts like the suctorial organ of a parasitic plant, and feeds the germ with food derived from the endosperm.

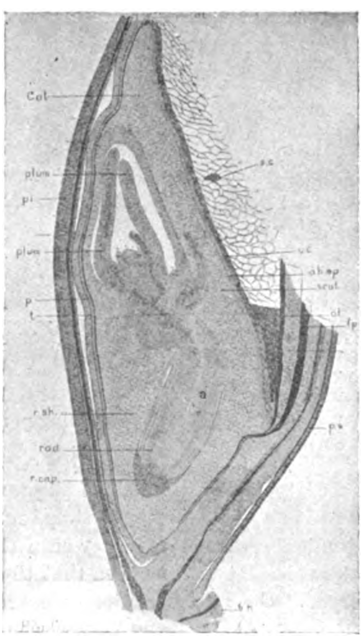

FIG. 6.—LONGITUDINAL SECTION OF THE GERM END OF A BARLEY CORN (HIGHLY MAGNIFIED).

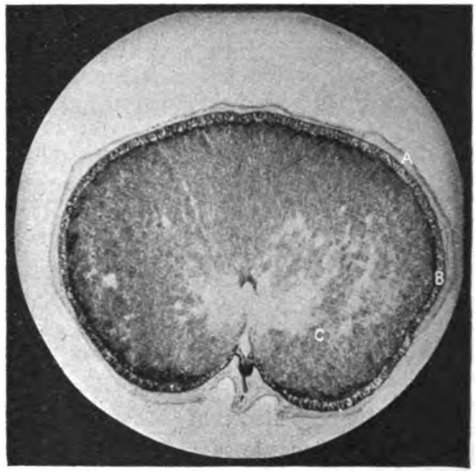

FIG. 7.—TRANSVERSE SECTION OF A BARLEY CORN.

A. Coverings of the corn.
B. Aleurone layer of endosperm.
C. Starch-containing cells of endosperm.

The endosperm of the barley corn is composed of two very different types of cells. The larger portion, constituting the white mealy part of the grain, is composed of thin-walled cells tightly packed with starch granules. Surrounding these cells is a layer of thick-walled cells situated immediately under the grain coverings which differ from the other cells of the endosperm not only in possessing thick walls, but also in not containing starch granules. These cells are called aleurone cells. The relative position of the two types of cells composing the endosperm will be seen in the photograph of a transverse section of a barley corn (Fig. 7). It is desirable however, to examine these two types of cells more closely as their constitution is of great importance with regard to the changes which proceed in the barley corn during germination. In a more highly magnified portion (Fig. 8)

of part of the endosperm it will be noticed that the walls of the starch-containing cells are thin and transparent. They are mainly composed of a form of cellulose closely resembling the cellulose of ordinary cotton-wool. When the starch-containing cells originally come into being during the development of the barley corn from the ovary of the barley flower, they are filled with living protoplasm in which starch gradually accumulates in the form of granules. As the seed approaches its ripening stage the starch granules increase in number and size until the cells are packed closely with them, and the remains of the original protoplasmic contents of the cells are crowded into the interstices between the starch granules (Figs. 9 and 10). Hence, when the corn ripens, the starch-containing cells are filled with starch

C. Thin-walled starch-containing cells comprising the greater part of the endosperm. The starch granules are visible lying embedded in the remains of the cell protoplasms.

granules lying embedded in the dried-up remains of the original protoplasm of the cells.

The nature of the aleurone cells constituting the outer layer of the endosperm will be more clearly seen in the enlarged photograph (Fig. 8). The cell-walls of these cells are very much thicker than the walls of the starch-containing cells, and are composed of somewhat different material. The aleurone cells contain no starch, but are filled with protoplasmic material exhibiting a granular appearance, and they usually possess very well-defined nuclei. I wish to call special attention to these cells, for they will be frequently referred to during this lecture.

FIG. 9.—TRANSVERSE SECTION OF OVARY OF A BARLEY FLOWER SHORTLY AFTER FERTILISATION.

Development into the future corn is in a very early stage. (Compare with Fig. 10.)

Comparatively little was known about the nature of the germination changes of the barley corn before the subject was investigated by Horace Brown and G. H. Morris in the

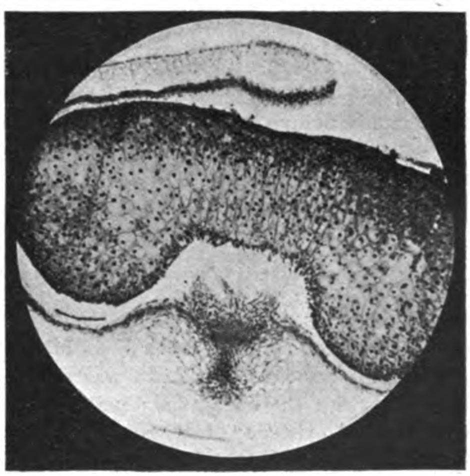

FIG. 10.—TRANSVERSE SECTION OF OVARY OF A BARLEY FLOWER AT A MORE ADVANCED STAGE OF DEVELOPMENT THAN FIG. 9.

Compare with Fig. 7, representing a transverse section of a fully-developed corn. (The section is stained and the cell-nuclei are visible as dark spots.)

year 1890.* At the time Dr. Graham delivered his course of lectures, it was recognised that the starchy part of the barley corn was the reserve food supply of the seed, and that it was utilised during the growth of the embryo; but, to judge from what one finds in Dr. Graham's lectures, little or nothing was known with regard to the ways and means by which the reserve food supply was utilised during germination. It should be remembered, however, that our modern knowledge of enzymes, or so-called soluble ferments, is more recent than Dr. Graham's lectures, and that in the absence of such knowledge it was almost impossible to obtain an insight into many of the physiological problems associated with the germinating barley corn. It is true the actions of diastase and those of some other ferments had been studied to some extent, and Dr. Graham recognised the importance of the diastatic activity of malt made

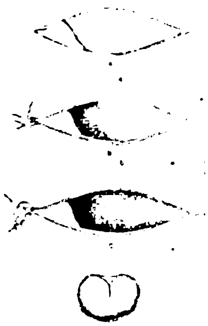

FIG. 11.—DIAGRAM SHOWING THE PROGRESS OF DISSOLUTION OF THE CELL-WALLS OF THE ENDOSPERM OF A BARLEY CORN AT DIFFERENT PERIODS DURING GERMINATION. (Disintegration of the cell-walls is indicated by shading.)

B. After six days' germination.
C. After ten days' germination.

(After Brown and Morris, *Journal of the Chemical Society*, 1890).

evident by starch transformation in the brewers' mashing process; but so little was Graham impressed with the knowledge then possessed regarding the existence of diastase as a specific enzyme, that he states "we are now all agreed, first, that there is no such body; and, secondly, that this [its action on starch] is not an action peculiar to diastase, even if such a body exists."

* Brown and Morris, "Researches on the Germination of the Gramineæ."—*Journal of the Chemical Society*, 1890, Vol. LVII., p. 459.

In 1890, when Brown and Morris took up the study of the germination changes of the barley corn, knowledge regarding enzymes and their actions had developed very considerably. Diastase was recognised as a specific enzyme capable of hydrolysing starch, and the existence of a considerable number of other enzymes such as invertase possessing specific actions was also well known. Moreover, it was conjectured that enzymes influenced the digestion of the food reserve of the barley corn for use of the embryo, but little or nothing was known concerning the manner in which this was effected.

In the course of Brown and Morris's investigations, it was shown that during germination of the barley corn, a progressive series of changes in the endosperm of the corn was noticeable as germination proceeds. These changes commence in the part of the endosperm nearest to the scutellum of the embryo. This part of the endosperm consists of a compressed layer of empty cell-walls of a similar constitution to the walls of the starch-containing cells (see Fig. 6). Here, immediately after germination commences, the first change is observed. These cell-walls swell and disintegrate, and partially dissolve away. Subsequently, as germination proceeds, the cell-walls of the starch-containing cells nearest to the layer of empty cells are also attacked and become disintegrated. As germination continues, this action slowly spreads through the endosperm, advancing more rapidly on the dorsal side, until in about ten days (see Fig. 11), it has modified the cell-walls throughout the whole length of the corn. As these changes proceed, the endosperm is softened and can readily be broken down by rubbing between the finger and thumb. This change constitutes the "mealiness," or "modification" which the maltster endeavours to produce in the limited germination period of malting, and is evidently induced by the disintegration of the cell-walls of the starch-containing cells liberating the starch granules contained within the cells.

Following on the disintegration of the cell-walls, the starch granules within the cells begin to show evidence of being attacked. This action commences in the starch granules which are situated nearest to the embryo and spreads through the grain, but it proceeds much more slowly than the action on the cell-walls previously described. In the ten to twelve days of germination which represents the usual length of the malting period, comparatively little of

the starch is acted on, although the walls of the starch-containing cells usually become disintegrated during this time throughout the whole length of the grain. The maltster, of course, does not wish to lose more starch from his grain than is necessary during the short period of germination which constitutes the malting process. If, on the other hand, the process of germination is allowed to proceed in an unrestricted manner, as it does during natural growth, complete solution of the starch takes place during the time taken for full development of the germ into the complete young plant.

Turning now to a consideration of the constitution of the embryo in connection with germination, physiologists had for some time regarded the so-called epithelial layer of the scutellum of the embryo—the layer of cells which forms the extreme limit of the scutellum immediately in contact with the endosperm (see Fig. 6)—as the means by which the nutritive material of the endosperm was absorbed and transferred to the growing embryo. It was obvious, in fact, that the nutritive material derived from the endosperm must pass through this layer of cells before it could be transferred to the growing embryo, for the layer is continuous over the whole surface of the scutellum. Brown and Morris, however, formed the opinion that this layer of cells possessed, not only absorptive functions, but also secretive ones; that, in fact, it was a specialised organ of secretion common to all seeds of the grass family, and one which enabled the embryo of these exceptionally constructed seeds to make use of the food reserve stored in the endosperm in a manner not previously recognised in any other class of plants.

Cytase, an enzyme which plays a conspicuous part in some of the physiological processes of plant life, is a so-called unorganised ferment which has the power of attacking and dissolving cellulose. Diastase, on the other hand, is an enzyme which attacks starch, converting it into soluble sugar. Arguing from what we have seen with regard to the changes which go on in the endosperm of the barley corn during germination, it seemed probable that the epithelial layer of the scutellum might function as a secreting organ, generating both diastase and cytase for the purpose of digesting the solid food-constituents of the endosperm, rendering them soluble and in a fit state to be absorbed as nutriment by the young embryo. If so, it might be anticipated that the solution of the cell-walls of the starch-containing cells which is observed during germination of the barley corn, would precede the action of diastase on the starch granules, for enzymes are not readily diffusible bodies, and the cell-walls of the starch-containing cells, previous to disintegration, would tend to hinder the advance of diastase.

Brown and Morris proceeded to put their conjecture to the test of experiment. I have already mentioned that the embryo and endosperm are not directly connected the one with the other; they are merely pressed one against the other, and there is no difficulty in separating the two without damage to either. These conditions make it quite easy to investigate the physiological processes of the embryo. If the embryo is carefully dissected from a barley corn it will grow under suitable conditions, apart from the endosperm, for a considerable period of time. For instance, if separated embryos are grown under conditions in which they are supplied with water only, they develop a short plumule and short rootlets at the expense of a small amount of food reserve originally present in their cells. In a brief time, however, their growth is arrested and they die of starvation. If, on the other hand, they are supplied with water containing cane-sugar, one of the most favourable carbohydrate foods for the growing germ, they develop into plants with green leaves; and if, in addition to cane-sugar, suitable nitrogenous and mineral food is also given, embryos may be reared to perfect plants by means of this "bottle" type of infant feeding. Experiments like these demonstrate that the embryo of the barley corn is enabled to grow at the expense of such carbo-hydrate and other nutriment as it obtains from the digested endosperm; but the special point Brown and Morris desired to investigate was whether the epithelial layer of the embryo was an organ capable of secreting enzymes for the purpose of digesting the endosperm. Experiments were conducted in which excised embryos placed with their scutella resting on moist barley starch were allowed to grow in this position. In every case distinct action on the starch-granules was observed. By means of these and other experiments of a somewhat similar nature, it was found that a starch-dissolving ferment was secreted by the scutellum of the embryo. Moreover, it was shown quantitatively that an increase in amount of the starch-dissolving ferment or diastase takes place as the embryo develops.

Somewhat similar experiments were also

made to ascertain if the embryo generated a cellulose-dissolving ferment during its growth. In these experiments embryos were placed with their scutella downwards on fragments of filter paper consisting of cotton fibre. After a little time the fibres of cellulose exhibited distinct evidence of solution from the action of a cellulose-dissolving ferment. These experiments were further confirmed by others, in which embryos were grown on thin sections of the endosperm of a barley corn. In these experiments it was again found that the cellulose composing the walls of the starch-containing cells of the endosperm was disintegrated by a cellulose-dissolving ferment secreted by the embryos.

But, so far, although the evidence brought forward by Brown and Morris indicated that the scutellum of the growing embryo secreted both diastase and cytase, it did not definitely locate the production of these enzymes to the particular layer of columnar epithelium cells which presents the appearance of a secreting organ (see Fig. 6 "ab ep"). This question was investigated by means of experiments with embryos from which the epithelial layer of cells was removed by dissection, an operation which can be done without serious injury to the vitality of the embryo. The results of these experiments indicated that, following removal of the epithelial layer, the embryo is incapable of secreting either diastase or cytase.

From the results of the investigations referred to, Brown and Morris arrived at the conclusion that the epithelial layer of the embryo of the barley corn and other grass seeds acted as an organ capable of secreting diastase and cytase, and that its purpose in the economy of the seed was to render the solid constituents of the endosperm soluble and capable of being absorbed by the embryo as food. The endosperm of the barley corn itself they regarded as being inert and without life; all the changes taking place in it, whether on the malting floor during restricted germination, or when the embryo develops into a fully developed plant and the endosperm is completely digested, they attributed to the action of enzymes secreted by the embryo.

Brown and Morris's investigations of the changes which take place during the germination of the barley corn was the first work to throw much light on the subject, and it constituted a marked advance in our knowledge of the scientific principles underlying the malting process; but the conclusion of these authors that the digestive changes in the endosperm originate solely in the embryo, and that the endosperm of the corn does not contribute in any way towards self-digestion, was viewed unfavourably by some botanists. Brown and Morris's conclusion indicated that seeds of the Gramineæ differ in a very marked manner from seeds of other orders of plants in the way in which they utilise their food reserve. No doubt the anatomy of the grass seed differs considerably from that of other seeds, but some botanists hesitated to accept a conclusion which differentiated the physiological processes accompanying the germination changes of the grass seed from those of other seeds in such a marked manner. Investigations in connection with this point were undertaken by various Continental botanists. Of these Haberlandt obtained results which appeared to indicate that the aleurone layer of the endosperm of the barley corn possessed the property of secreting diastase in addition to the embryo.* This conclusion, however, seemed to require confirmation, and H. Brown, in conjunction with Escombe, reinvestigated the question in 1898.†

The cells of the aleurone layer of the ripe barley corn had long been known to differ from the starch-containing cells of the endosperm in so far as they exhibit the characteristic appearances of life. The original nuclei of the starch-containing cells of the endosperm, which are very conspicuous in the early stages of the development of the corn, become disintegrated or deformed as the corn matures, and when the corn is quite ripe the appearance of the remains of the nuclei suggests complete loss of life. On the other hand, the nuc'ei of the aleurone cells of the mature corn are very well marked, and their appearance suggests that the cells are in active life. There seems to be, therefore, a marked difference in the nature of the two types of cells composing the endosperm—the starch-containing cells present the appearance of being functionless and dead, and the cells of the aleurone layer appear to be in active life. Histological evidence, therefore, seemed to support the view which had been advanced by Haberlandt that the aleurone layer might play a part in the digestive changes which take place during germination of the barley corn.

I regret that I have no time to refer other than briefly to the investigations of H. Brown and Escombe with regard to the action of the

---

* Berliner deutschen botanischen Gesellschaft, 8. 40.

† *Proceedings of the Royal Society*, 1898, Vol. LXIII.

aleurone layer of the barley corn during germination. It must suffice to say that their work confirmed Haberlandt's conclusion that the aleurone layer of the endosperm functions as an organ for the secretion of diastase in addition to the epithelial layer of the embryo. Further, they were enabled to demonstrate that not only does the action of the aleurone layer resemble that of the scutellum of the embryo in secreting diastase, but it also resembles it in secreting an enzyme of the nature of cytase capable of acting on the walls of the starch-containing cells of the endosperm.

The extended investigations of Brown and Escombe, therefore, indicated that the original view of Brown and Morris regarding the germination changes of the barley corn required modification. The latter investigators considered that the digestive changes which take place in the barley endosperm during germination were occasioned by enzymes secreted by the embryo, and that the endosperm itself played no active part in these changes. It was found now that, in addition to the action which the embryo exerts in connection with the digestive changes of the endosperm, the aleurone layer of the endosperm also contributes to the production of these changes.

The evidence which has been brought forward to show, on the one hand, that the embryo of the barley corn during germination secretes diastase and cytase through the agency of the epithelial cells of the scutellum, and, on the other, that the aleurone layer of the endosperm under similar conditions also secretes similar enzymes, appears to be quite conclusive, and it is somewhat difficult to understand how any one can study the experiments on which these conclusions rest without becoming convinced of their general accuracy—nevertheless, during the past few years a growing inclination has been shown in some quarters to disregard the experimental evidence which has been brought forward in support of these statements, and to fall back on the old conception that the starch-containing cells of the endosperm of the barley corn are entirely self-digestive. The upholders of this view appear to derive some support from the investigations of the Continental workers, Puriewitsch, Grüss, and Bruschi, but I must confess that I can find nothing in the work of these investigators which materially affects the experimental evidence brought forward by Brown and Morris, Haberlandt, and Brown and Escombe. It may be a question open to doubt whether the starch-containing cells of the endosperm of the ripe barley corn are dead, or whether they still retain traces of vitality sufficient to influence to some slight extent the changes which proceed during germination. But I fail to find any evidence in the work of Puriewitsch, or the other Continental investigators named, which seriously questions the view that the embryo and the aleurone layer of the endosperm play a leading part in the digestive changes of the germinating barley corn. The subject is, however, one of much importance, not only from a botanical point of view, but also in connection with technical malting, and it is most desirable that doubt of any kind in connection with it should be removed. I am pleased to say, therefore, that recently some very interesting investigations* have been carried on in connection with the question by Dr. F. Stoward, an old student and fellow worker in my laboratory, which throw a good deal of light on the enzyme-secreting properties evidenced by different parts of the barley corn. The main object of Stoward's investigations has been to ascertain definitely whether the enzyme-secreting powers of the embryo, and of the aleurone layer of the barley corn, are mainly responsible for the digestion of the food reserve during germination, as is contended by H. Brown and Escombe, or whether the starch-containing cells of the endosperm are self-digestive, according to the views of Bruschi and others.

It was imperative, in order to make any real advance on the investigations which had already been carried out in connection with these questions, to attack the problem quantitatively, for measures of the amounts of enzymes secreted by particular parts of the germinating corn must be obtained before any definite conclusion can be formed regarding the influence exerted by these different parts during germination. Stoward commenced his study by determining the relative amounts of diastase secreted by the embryo alone, by the aleurone layer alone, and by the starch-containing cells of the endosperm.

The experiments by which these determinations were made had to be carried out under conditions of exceptional difficulty. Not only was it necessary for portions of the barley corn such as the embryo, or the aleurone layer, employed in the experiments to be kept alive and in a healthy condition during periods of perhaps several weeks in order to study

* These investigations will shortly be described in the *Annals of Botany*.

their actions, but the experiments throughout their course had to be conducted under perfectly sterile conditions. I should like to describe the manner in which these experimental difficulties were met, but a detailed account of Stoward's work would be out of place here. It must suffice to give the conclusions Stoward has arrived at from the results of his investigations. These may be briefly summarised as follows:—

The original conclusion of Brown and Morris that the embryo during germination secretes diastase and cytase in comparatively large quantities is fully confirmed, as is, also, the conclusion of Brown and Escombe that the aleurone cells of the endosperm secrete similar enzymes. Probably the part played by the aleurone cells in the digestive changes during germination is somewhat greater than that of the embryo, but the combined actions of the aleurone cells and the embryo are sufficient to account for the whole of the observed changes. When the starch-containing portion of the endosperm, apart from the aleurone layer and the embryo, is placed under conditions favourable to self-digestion, but little action is observed even after several weeks, and the character of the feeble action which proceeds may be traced to the influence of residual enzymes pre-existing in the starch-containing cells of the endosperm. No evidence was found which tended to show that the starch-containing cells are capable of secreting digestive enzymes.

I mentioned before, when referring to H. Brown and Morris's original view that germination changes in the barley corn were effected solely by the embryo, that some botanists were reluctant to accept this view, because it dissociated the seeds of the Gramineæ in a very marked manner from the seeds of all other plants. But when it is recognised that the aleurone layer of the barley corn, itself a portion of the endosperm, takes part in the germination changes of the corn, the botanical difficulty vanishes. The grass seed need no longer be regarded as differing essentially from other seeds—it is merely a highly specialised seed. The aleurone layer is a portion of the endosperm which seems to have become differentiated for the purpose of secreting enzymes required for the digestion of the food reserves of the seed. The secretory epithelium of the embryo also appears to have become specialised as an organ for secreting similar digestive enzymes. The starchy part of the endosperm seems to have lost the property of self-digestion, but this loss is amply compensated by the digestive activity of the aleurone layer and the embryo.

So far, when speaking of the changes which take place in the barley corn during germination, I have only referred to the breaking down of the carbo-hydrate constituents of the endosperm—to the conversion of the food reserve of starch and cellulose into soluble diffusible carbohydrate material capable of assimilation by the growing embryo. It must not be forgotten, however, that conversion of the reserve protein matter stored in the endosperm also takes place during germination of the barley corn through the instrumentality of one or more proteolytic enzymes. The growing embryo requires nitrogenous food, and we know that transference of nitrogen-containing matter from the endosperm to the embryo is a marked feature of germination. For example, instances will be found in the following table* which illustrate how the nitrogen originally present in the endosperm of the barley corn migrates to the embryo at various stages of the malting process.

	Hungarian Barley.		Chevalier.	
	Per cent. N. left in endosperms.	Per cent. N. which has migrated to embryo.	Per cent. N. left in endosperms.	Per cent. N. which has migrated to embryo.
After steeping	100	—	100	—
Three days on floor	91·1	8·9	86·2	13·8
Five days on floor	82·8	17·2	83·0	17·0
Seven days on floor	71·2	28·8	82·8	17·2
Nine days on floor	64·6	35·4	67·8	32·2

* *Transactions of the Guinness Research Laboratory*, Vol. I., Part II., 286.

It will be seen that about thirty-five per cent. of the endosperm nitrogen passes into the growing embryo during nine days' germination on the malting floors.

The work of Weiss,* and that of other investigators, tends to show that the proteolytic action which takes place during germination probably results from the actions of two distinct enzymes, one of the nature of a peptase and the other of a tryptase. But notwithstanding the considerable amount of work done in connection with the proteolytic enzymes present in the germinating barley corn, we are still very much in the dark as to the manner and place of their origin in the corn. We have seen that the embryo and the aleurone layer of the grain secrete cytase and diastase, and by analogy one would be inclined to look to the same parts of the corn as the probable source of the proteolytic enzymes, but at present direct evidence in support of this view is wanting. The question is one of many connected with the biological processes of the germinating barley corn which still await elucidation.

Among the points of difference which distinguish the highly specialised seeds of the Gramineæ from other seeds is one associated with the solution of the endosperm-constituents during germination which deserves special attention, as it is of considerable importance from both the scientific and technical points of view.

During the germination changes in an ordinary seed, solution of the food reserve and transference of the food to the growing embryo is the direct work of living cells, and the actions throughout their whole course are, so to speak, under the rule and protection of living protoplasm. But in the germinating grass seed a different condition of things is noticeable, more especially in the later stages of germination. We have seen in the case of the germinating barley corn that the insoluble starch and protein matter of the endosperm are converted into soluble diffusible constituents capable of being absorbed by the embryo as food. The embryo, however, does not assimilate this food as rapidly as it is produced, and it accumulates to some extent in the cavity of the endosperm enclosed by the seed coverings. Now, under these conditions there must be opportunity for loss of some of the accumulated food products by diffusion through the seed coverings, unless the seed is specially provided with means to prevent it—for material such as sugar, which constitutes the bulk of the dissolved food products, usually diffuses readily through thin cellular membranes such as the coverings of the barley corn. Under these conditions it is a matter of peculiar interest to find that the testa, or inner thin skin of the barley corn, behaves in quite an abnormal manner with regard to diffusion—in fact, it constitutes the most remarkable "semi-permeable membrane" at present known. Not only does it obstruct diffusion of such bodies as sugar and other soluble food products present in the germinating corn—thus rendering it an efficient protection for the food supply of the embryo—but it also acts as a semi-permeable membrane with regard to such highly diffusible bodies as sulphuric acid, hydrochloric acid, and very many mineral salts when in aqueous solution.

I pointed out a short time ago,* when calling attention to the remarkable property of semi-permeability possessed by the seed-coverings of the barley corn, that hitherto it had been supposed that among naturally-formed membranes the property of semi-permeability was confined to those composed of living protoplasm, and was absent from non-living structures such as the coverings of the barley corn; but in these coverings we now find evidence of the most marked semi-permeability. For instance, if dry barley corns are immersed in a 5 per cent. solution of sulphuric acid, the water alone of the solution is absorbed by the grain, the acid outside being increased in concentration in a manner proportional to the water absorbed by the barley corns. Nor is this so in the case of a 5 per cent. solution of acid only. With solutions of varying strengths of acid up to 36 per cent. a result is obtained which is similar in kind but different in degree, for as the acid solution becomes more concentrated, less water enters the seed. This difference is to be ascribed to the higher osmotic pressure of the stronger solutions. In short, a seed of barley behaves as a cell completely enclosed in a semi-permeable membrane, this membrane being the testa, or inner skin of the corn.

This property of semi-permeability is found to extend to the testa, or inner seed-coverings, of all the species of Gramineæ yet examined, and it appears reasonable to suppose that its special value to the seed is to protect the food-supply of the embryo, which would otherwise be open to loss owing to the highly-specialised nature of the seeds of the grass family.

It is interesting to note also, in connection

* *Annals of Botany*, 1907, Vol. XXI., p. 79.

with this unique semi-permeable covering of the barley corn and other grass seeds, that nature appears to have made special arrangements in shaping the seed to protect the covering from rupture, which would, of course, destroy its efficiency. When the dry barley corn absorbs water previous to germination, it swells to the extent of about 50 per cent. of its original volume, but danger of rupture of the coverings is avoided by the re-entering ventral furrow which characterises the corn. This furrow, it will be noticed (see Fig. 12) permits very considerable expansion of the contents of the grain without endangering the continuity of its coverings; it acts as a sort of expansion safety-valve.

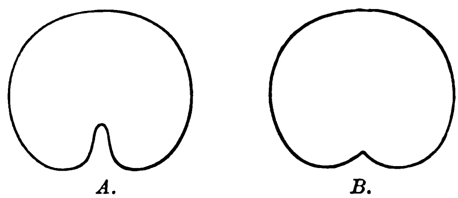

Fig. 12.—Diagram of Transverse Sections of Dry and Steeped Barley Corns.

A. Dry corn.
B. Steeped corn.

But the unique and hitherto unsuspected semi-permeable nature of the inner skin of the barley corn just referred to, is even less remarkable than one which came to light in the course of further investigations.* These revealed the power of selective permeability of the skin in the presence of certain solutes. Thus, if barley corns are immersed in a mixture of solutions of mercuric chloride and sulphuric acid, the former salt passes through the seed-coverings and diffuses throughout the whole seed, while the sulphuric acid is kept outside. In a similar fashion, acetic acid and the fatty acids generally are able to pass through the seed-coverings; but the salts of these acids, such as sodium acetate, are excluded. More remarkable still is the fact that whereas acetic acid enters and diffuses through the seed very readily, the corresponding amino-acid, glycine, will not enter at all. Aqueous solution of ethyl alcohol, aldehyde, acetone, and ethylic acetate diffuse into the seed rapidly; but in the anhydrous state these liquids are excluded. The only explanation of this property of selective-permeability which can be suggested at present is that it is related in some way to the manner in which the molecules of the various solutes are united with the molecules of the solvent water. The subject is a very promising field for further investigation.

In this lecture I have been able to refer to a few only of many subjects of scientific interest associated with the malting process, but I think I have said enough to indicate what wide fields for future investigation still lie open in this direction. Probably the germination changes of the barley corn have been studied more thoroughly that those of any other seed, and yet we appear to have only just penetrated the fringe of the subject at present. Much more knowledge is required before malting is placed on a thoroughly sound scientific basis.

COMMERCE AND THE UNIVERSITIES.*

INDUSTRIAL FELLOWSHIPS.

The publication by the Royal Commission for the Exhibition of 1851 of a scheme for the award of industrial bursaries to young men who, after a course of training in a university or approved technical college, desire to enter engineering, chemical, or other manufacturing works, is another indication of the desire of educationists to establish a link between education and industry. This scheme is based on the assumption that college-trained men are not able as a rule to obtain remunerative employment in industries immediately after the completion of their college course. Its main characteristic, however, is to lead the students to the manufacturers. The contrary movement, to bring the manufacturers to the universities, presents an equally important problem, which in a large measure remains unsolved in this country, and a complementary scheme which would encourage this movement is much needed.

Such a scheme is in operation in the University of Kansas, under the enlightened direction of the Professor of Industrial Chemistry, Robert Kennedy Duncan.† A reference was made to the scheme in the evidence of Dr. Nicholas Murray Butler, President of Columbia University, New York, before the Royal Commission on University Education in London, but so far as is known details have not been published on this side of the Atlantic. The recognition of the need for a thorough general training in science before a student is allowed to specialise in applied science, is an extremely important characteristic of Professor Duncan's scheme. He decided, without hesitation or reservation, that the scheme should only apply to highly-trained university graduates.

* Reprinted, by permission of the Editor, from the *Times*.

† Professor Duncan is a member of the Royal Society of Arts.

The conditions of American manufacture were favourable to the establishment of the scheme. Writing in the *American Journal of Industrial and Engineering Chemistry* for August, 1909, Professor Duncan says:—

"Two years ago . . . conditions were changing rapidly. The unexampled and wasteful production of the country was bidding fair to result in over-production; in the practice of business intrigue no manufacturer had anything to learn from another; the wealth of raw material had in a large measure been aggregated into the holdings of a few men who would release them only at an onerous and distressful rate; the tariff, high as it was, was unable to exclude many articles made under scientific supervision, and the tariff itself lay and lies in increasingly unstable equilibrium. These facts convinced me that American manufacture was approaching a crisis, and that there would soon be a realisation that safety in manufacture could be gained only through efficiency."

In what way was this efficiency to be achieved? The American manufacturer—and the same may no doubt be said of the British manufacturer—is generally incapable of organising an efficient research department in his own works. He lacks the knowledge and experience necessary for the work; he cannot judge the qualifications of the men he should employ; he cannot estimate the expenditure necessary for the work; and, lastly and chiefly, he does not know how to treat the man of science by giving him power and trust.

The Kansas University Scheme.

With these facts before him, Professor Duncan devised in 1907 his scheme of Industrial Fellowships. The Fellowships are tenable in the Chemical Department of the University of Kansas by students appointed by the university, and the emoluments are provided by manufacturers. To illustrate the conditions under which the Fellowships are held, those attaching to a Fellowship (No. 7) established by a glass company may be taken as typical. The object of the Fellowship was investigation into the optical properties of glass in relation to its chemical constitution. The Fellow, who was appointed by the university, contracted to devote the whole of his time to this investigation, with the exception of three hours a week, which he gave to teaching in the university, in return for which he was exempted from the payment of university fees. The tenure of the Fellowship was for two years, and the emoluments, $1,500 a year, were provided by the company. The essential characteristics of the scheme remain to be mentioned. All discoveries made by the Fellow during the tenure of the Fellowship become the property of the company, subject to the payment of 10 per cent. of the net profits to the Fellow; and any patents taken out by the Fellow are assigned to the company. The Fellow is allowed to publish any results, the publication of which, in the opinion of the company, would not injure their interests. At the end of the tenure the Fellow is required to present to the university a complete monograph on the work done, and, after the expiration of three years, the university is at liberty to publish the results for the use and benefit of the people.

It will be seen that by this ingenious arrangement the interests of all parties are safeguarded. To the university the influence of the Fellows and their teaching work are valuable assets, while its character as a public institution is protected by the right to publish the results of researches conducted within its walls after the lapse of three years. The Fellow carries on his work under greater advantages than are possible in a factory. He can consult the university professors, specialists in all departments of knowledge, in any difficulties that may arise, and he has the stimulus of working alongside others with similar objects; the resources of libraries and museums are placed unreservedly at his disposal; he has the opportunity of carrying out his laboratory experiments under factory conditions in the donor's works; and he becomes an expert in his particular study, with excellent prospects of remunerative employment in the factory of the company or elsewhere. Lastly, the conditions have proved to be satisfactory to the manufacturer.

Results Attained.

Some particulars may now be given of the researches which have been carried out under this scheme. The general conditions attaching to the Fellowships have in all cases been identical, though the emoluments have varied. The following is a list of the subjects investigated by the first ten Fellows appointed:—

1. The chemistry of laundering.
2. A search for a new diastase (otherwise, an attempt to make a new fodder on scientific principles).
3. An attempt to utilise the constituents of waste buttermilk.
4. The chemistry of baking. (This Fellowship was established by the National Association of Master Bakers.)
5. The constituents of crude petroleum.
6. The enamelling of steel tanks for chemical operations on a large scale.
7. Optical properties of glass.
8. New utilities for Portland cement and improvements in its manufacture.
9. Certain glands of deep-sea mammals.
10. New utilities for ozone.

From the details which have been given of the conditions attaching to the Fellowships it will be understood that information cannot, in all cases, be given as to the results achieved by the researches. It is significant, however, that Fellowship No. 1 was continued for a further period at double the value, with an offer from the donors either to take the Fellow into their factory or to continue the Fellowship with increased emoluments. The second Fellowship was continued for a third year.

This Fellow discovered a method by which the high diastatic content of alfalfa could be conserved in fodder. Fellow No. 3 discovered a method of utilising stale bread in the manufacture of new bread, and a method of standardizing the manufacture of salt-rising bread.

Provided the co-operation of manufacturers could be obtained, there is no apparent reason why a scheme based on the same principles could not be successfully worked in this country.

ARTS AND CRAFTS.

The Report on the Royal College of Art. — The most interesting artistic event of the month is the publication of the Report of the Departmental Committee on the Royal College of Art. The main recommendations of the committee have been published in the daily papers, and by now most people interested are familiar with them. They show throughout a desire to co-ordinate the art teaching of the country with its most important industries, and to encourage design for manufacturing processes more than has been done in the past. Shortly, they suggest that the Royal College of Art shall in the future be looked upon as a post-graduate college, whose students will be recruited from the schools of art in the great provincial manufacturing centres; and that liberal provision should be made for scholarships tenable at these provincial colleges. By this arrangement we should get the ordinary art schools, which would send the best of their pupils on to the provincial colleges, which would in their turn send on their cleverest students to the Royal College.

As one reads the report, one cannot but be struck by the good sense and moderation of the document, and the evident desire of the members of the committee to place the teaching of design (it is with design that the report is mainly occupied) on a satisfactory and common-sense basis. They are evidently well aware that the present system (or want of system) of training designers for manufacturing processes leaves much to be desired, and they have done their utmost to suggest lines on which it can be bettered. Their suggestions are sane and practical, and in most respects admirable, but there come points where they betray the fact that among the eight members who sign the report (though there are two who are, amongst other things, designers) there is not one whose primary business in life is designing for manufacture.

If the recommendations of the committee are carried out they should revolutionise the whole system of design teaching in this country, and in many ways to very good purpose. There are, however, points which cause one to fear that in making the teaching of design severely practical, art may be rather ousted by commercialism. It is true, of course, that of late, in what should be schools of industrial art, we have heard too much about art and not enough about industry, but it is possible to go too far on the other side. *Apropos* of the training of teachers, a good deal is said in the report about the weakness of students in literary attainments, and suggestions are made towards remedying it. Nothing is said about the literary education of the designer. And, in a way, that is to the good. There is certainly no reason why in order to be a good designer a man should have passed, or be able to pass, say, the Oxford or Cambridge Local Examinations. But, on the other hand, it is necessary that he should be in some sense a man of education. It is partly because they are not that, that many men, who up to a certain point are competent designers, fail to do really first-class work.

Again, the report speaks of the advisability of students at the end of their career spending time in studying at the Victoria and Albert Museum and elsewhere, but it seems to contemplate this merely for the select few who are qualified to undertake a post-graduate course, and for them at the extreme end of their training. Now, if the majority of design students were men and women of thoroughly sound general education, brought up in highly-cultured homes or amongst surroundings which encouraged their powers of artistic perception, that might be all very well. But, as the report itself shows, they are not. If you take a very imperfectly educated boy of the artisan or lower middle class, and turn him into the local art school, to be taught (as the report again suggests is probable) by an art master whose own general education is defective; if at the end of a couple of years you transfer that youth to a provincial college, where he will specialise in design for some manufacture, under art masters with whom are associated representative manufacturers and artisans connected with that industry; you may possibly make him by the end of his time a good hack designer. But can you reasonably expect him to be a man of such strong and well-trained artistic taste that he can and will, in spite of the many difficulties which beset a trade designer, persistently and successfully do the best kind of work? There would surely be more chance of that if at an earlier stage in his career, before he had been thoroughly drilled in trade requirements, he could be turned into the Victoria and Albert Museum for a few months with a judicious guide, and shown at first, and then encouraged to see for himself, what the best men have done before him. Some of our big manufacturing towns, have, it is true, good museums, others have not. And no local museum *plus* a system of circulation, however good, can reproduce in the provinces the Victoria and Albert Museum. In that we have, undoubtedly, the greatest and most comprehensive storehouse of industrial art to be found in Europe—a storehouse of which it may be truly said that a real and intelligent knowledge of its contents would be a liberal education of just the kind of which a man who is to be a trade designer stands in need. Since we have the Museum, it is surely poor

economy not to use it to the full, and to regard it as a luxury for a few designers rather than as a necessity for all. It is to be hoped that the fact that the Royal College of Art has been conspicuously out of touch with industrial design will not blind those concerned with the training of the coming generation of designers to the fact that nothing better could be done for students, once they are competent draughtsmen, than to let them work at the Museum for a while.

National Competition.—A rather pathetic interest attaches to this year's National Competition Exhibition, for, though it is not the last of its race, it is the last but one that will be seen at South Kensington. Whatever may take the place of the existing regulations with regard to National Competition, the old system has received its death blow and, in consequence, this year's exhibition has lost a good deal of its importance. It does, indeed, show what is going on in the principal art schools throughout the country, but it cannot give as much indication as usual of what will be done in future years. There is no denying that the awards and the works shown at one year's exhibition have always exercised a very strong influence on the work of succeeding sessions—not, it is to be feared, entirely because the decisions given were looked upon as the best that could possibly have been made, but in large measure because students hoped to gather from them the kind of work which was likely to meet with success. It is just worth noting, in passing, that this little proceeding did not always turn out very satisfactorily, as the more wary of the examiners sometimes realised just what was happening. But, whatever may have been the exact causes of the influence of the National Competition Exhibition, it is plain that, for the next year or so, while the future of the exhibition itself is doubtful and the work of reconstructing the examination system of the Board of Education goes forward, the influence itself will be felt but slightly, even if it is not wholly inoperative. It remains, therefore, rather to see what this year's exhibition tells us of the actual state of design teaching than to point out what the present tendencies seem to foretell. There are two points about this year's work which may be noted with a good deal of satisfaction—the number and excellence of the studies of historic styles of ornament, and the decorative quality and the understanding of the requirements of design shown by a good deal of the work sent in, not only under the headings of "Designs Based on the Flowering Plant" and "Plant and Three Designs," but also of "Studies of Plant Form." If students can only be brought to realise the importance of studying both plant form and ancient ornament, the less brilliant of them will be on the road towards producing passable designs, and the really clever designers will have that grounding which it is necessary to acquire if they wish their own inherent powers to develop later to the full extent of their capacity. There is just one caution, however, which must be added: study both of old work and of nature is good, but it must be combined with the appreciation of methods of workmanship. It may seem almost unnecessary to say that nowadays, but one of the best, if not the best of the sets of designs based on a flowering plant, made no mention of what the designs were for—nor did the patterns themselves make it plain. The students as a whole, however, show in their studies, whether made from nature or from old work, a far better appreciation of the kind of drawings which will be useful to a practical designer than they did a few years ago.

When we turn to actual designs, a noticeable feature this year, as last, is the number of fairly simple practical patterns coming, for the most part, from the great manufacturing centres which have obtained small awards. Stencilled hangings seem rather to have taken the place of the printed muslins so popular some years ago, and to have attracted, like them, somewhat disproportionately high awards. In some of the crafts the standard is distinctly higher than it used to be. The best of the gold and silver work is accomplished craftsmanship, and, though the awards for bookbinding are not so high as they have sometimes been, and the designs are as a whole somewhat lacking in ingenuity, the workmanship is usually very good. The lettering, too, is as a whole very satisfactory, more especially the bold work on a large scale, but there is not so much script as in previous years, and some of the illumination is unnecessarily hard and archaic. Among interesting exhibits which do not fall into any well defined class, may be mentioned the delicately tinted vellum caskets and boxes from Armstrong College, Newcastle, and the really beautiful embossed leatherwork from Birmingham (Margaret Street).

EMPIRE NOTES.

A Congress of Empire Universities.—It is proposed to hold a congress of representatives of all the universities of the British Empire, in London next year, for the purpose of considering the question of organisation, the relationship of the universities to teachers, undergraduate students and schools, and other subjects of academic interest. The secretary of the Congress is Dr. R. D. Roberts, the Registrar of the University Extension Board of London, and an influential committee has been appointed to make the necessary arrangements, with Prince Arthur of Connaught as president. Dr. Roberts has just returned from Canada, where, at a conference called for the purpose, the programme of the London Congress was discussed. Nineteen universities, says Dr. Roberts, were represented at the conference. He found that the most interesting feature of the conference was the opportunity it afforded for the discussion of matters of purely

local concern, upon which the views of the universities, as a whole, had never been focussed before. The result, he considers, is almost certain to be the establishment of local conferences, a fact which he had come to realise in connection with the meetings of the Home Congress Committee. This committee, which consists of the vice-chancellors and other representatives of the home universities will, he evidently thinks, be the means of bringing these universities into closer relationship with each other, while the proposed Congress will widen the interest taken in higher educational, and particularly university, movements, to the advantage of the whole Empire.

The Mixture of Races.—The recent Universal Races Congress held in London, which, as an assembly, was like Joseph's coat of many colours, had under discussion the miscegenation of the races, a subject which naturally evoked many differences of opinion. What British South Africa thinks about that question may be judged from the decision of the Supreme Court of Cape Colony, in connection with a case brought before it during the last few weeks. It appears that the children of a European, who had married a coloured woman, were admitted to a public school in the district of Gordonia. To this proceeding objections were raised by the parents of the European children attending the school. The school committee, therefore, refused to allow the further attendance of the coloured children. The matter was thereupon submitted to the Supreme Court, on the general question of the rights of coloured children to attend the public schools of the State. The presiding judge refused to compel the school committee to readmit the children, and his decision was upheld by the full bench. This case, therefore, will decide the question as to the exclusion of the children of mixed marriages from the State schools, a question which has been for some time under consideration, as attempts have frequently been made, in some instances with success, to secure the admission of children of coloured or mixed parentage to schools reserved for the children of European parents. Provision has been made for coloured children in separate public elementary schools, and to this provision the authorities evidently intend to adhere.

The Development of the Katanga.—A Consular report has just been issued by the Board of Trade on the Katanga. It is most informative, and gives many interesting facts and figures relative to the industrial and commercial development of this comparatively little known region of Southern Africa. The Katanga, as its name implies, is a copper country, and some of the native mines have been working for centuries. The entire territory appears to be mineralised, and the fluxes for smelting are found almost side by side with the metals. At some of the new locations, the ore bodies are of enormous size. Gold and tin are being profitably worked in various parts, while diamond pipes are known to exist on the Kundelunga River. The soil of the river valleys is rich and fertile, and capable of producing almost anything. These valleys should lend themselves to culture of every description, in addition to maize, which yields a large return and for which the market is unlimited, fruit farming, tobacco growing, cotton and coffee planting, should prove profitable undertakings. Both cotton and tobacco are indigenous, and are cultivated by the natives on a small scale. Pig raising is possible everywhere. Lucerne would yield three crops per annum. Oats would probably do well, and wheat has been successfully grown in one or two instances. There is said to be an opening for fibre plantations, for fibre is found everywhere on ant-hills, which are a distinctive feature of the landscape. Outside the mining camps native labour is plentiful and cheap. It is computed that the money already invested in various operations is not less than £10,000,000. With regard to imports, although the statistics are incomplete, the United Kingdom is known to lead the way, while South Africa last year supplied goods to the value of £268,022, of which the greater part must have gone from England. It is roughly calculated that 70 per cent. of the general merchandise is obtained from one part or another of the British Empire; a fact that shows an excellent beginning has been made.

The Cultivation of Cotton in the Transvaal.—The development of the cotton-growing industry in the Transvaal has recently been making excellent progress. For some time past experts have been endeavouring to induce farmers, whose properties are situated in that part of the country where the soil and climate are such as will give the plant a fair trial, to make tests. Many farmers who have made these tests have been convinced that good crops are to be obtained from their land, and that this branch may possibly be made a profitable adjunct to their general farming operations. The efforts of the Government experimentalists have been attended with striking results. A comparison between American-grown cotton and some from the Rustenburg experimental station shows that one variety (Bancroft) at least is well up to the mark. The American yield test gives forty-eight bolls of seed cotton to the pound, whereas that grown at Rustenburg yielded forty-three bolls to the pound. This is regarded by Manchester experts as eminently satisfactory, the more so when viewed in the light of the productions of former years. The question that is vexing the promoters of extensive cotton cultivation is not so much whether the cotton equals the American standard, but whether it can be made a commercial success. As to this, there appears to be a wide difference of opinion. It is asserted in some quarters that the demand for no other article is so far in excess of the supply as is the case with cotton. If this be true, it seems only reasonable to assume that if the cotton can be produced in sufficiently large quantities, a great

industry will be built up in South Africa in time to come. On the other hand it must be borne in mind that the United States of America has an established market for the product. Inquiries are being prosecuted into the cost of the various items which add to the price of the article from the time it leaves the grower till it reaches its market, such as railway rates, wharf dues, freight charges, brokerage, sellers' commission, and so forth. Until these facts are elicited, it will be impossible to arrive at anything definite as to the net profit that can reasonably be expected by the grower.

Natal Spas.—The hot springs of New Zealand have a wide reputation, but Natal has recently shown that springs of a similar nature are to be found within her borders. Not long ago springs were discovered rising from an island in the Tugela River. Now sulphur springs have been located near Greytown. The latter cannot be regarded as a new discovery, since many years ago they were known to exist by the Dutch community in Natal. The waters have been proved to contain similar chemical constituents to those of Harrogate and other popular European spas. The supply is plentiful, and issues from the rocks at the rate of some thousands of gallons per hour. As the climate of Natal possesses much to attract those whose health requires these healing waters, and having regard to the proximity to Europe, it is hoped in South Africa that Greytown will eventually become one of the largest and most prosperous resorts in the world.

Railway Progress in Western Australia.—The Premier of Western Australia, the Hon. Frank Wilson, C.M.G., who has just returned from his Coronation visit to this country, in a speech delivered a few days ago, stated that the earnings of the State railways of Western Australia for the financial year ending June 30th last, showed an increase of £207,085 over the previous year, the net profit for the year being £224,441. The new railways, opened during the past twelve months, to the goldfields and the agricultural districts, amount to 231 miles, while nine additional lines, representing 354 miles, had been completed, or nearly completed. The total railway mileage opened to January last was 2,384 miles. When all the lines now in course of construction and survey are finished there will be a total of 3,220 miles. The successful operation and development of the State railways by Australia, under the careful and economical management now employed in all the different States, furnish the advocates of the nationalisation of home railways with excellent arguments which have recently been advanced on account of the troubles in the railway world through which the country has just passed. The conditions, however, which obtain in new countries like Australia and New Zealand are so different from those of the old country that the cases are scarcely parallel. At the same time it is useful to note that State ownership, as at present illustrated in the progress and evident prosperity of the railways of our southern Dominions, is proving a distinct advantage to the communities they serve.

Canadian Dividends for British Shareholders.—Attention has been drawn in these columns to the opportunities for the investment of British capital in Canadian undertakings. It has also been pointed out that British investors have a larger interest in Dominion securities than Canadians and Americans. In view of this it is interesting to note some figures given in a recent issue of the *Monetary Times* of Toronto, which indicate the amount paid in dividends to British investors as compared with that paid in the Dominion itself. It appears that £695,750 crossed the Atlantic after July 1st of this year, this being six months' interest on Dominion securities. At the same time the amount paid in Canada for the same period was approximately £8,000. The United States of America have but a small share in the total amount paid. These figures demonstrate the faith held by the people of these islands in the future of the Dominion. The bond issues of the Western Provincial municipalities, which offer a comparatively low return, are exceedingly popular, and of these British investors have absorbed 65 per cent., against 1 per cent. taken up in the United States and 34 per cent. in Canada.

CORRESPONDENCE.

TOBACCO, COTTON, AND CASTOR OIL CULTURE IN SOUTH AFRICA.

I have received a copy of the *Journal of the Royal Society of Arts* of March 13th, 1896, containing an article by Mr. C. Tripp on the cultivation of tobacco in Sumatra, which proves most interesting and instructive, and contains invaluable information.

Unhappily, our Government does not sufficiently encourage farmers to depart from their old-fashioned ways of agriculture, nor is instilled into them the spirit of venture into new methods of farming to move with the times. This by no means implies that the Government must spoon-feed the agricultural community, but it might to advantage impart knowledge by means of lectures and practical proof, and so educate a most conservative people, slow to depart from the ways of their forefathers.

A few years since, tobacco culture in the Transvaal and in the Orange Free State appealed to me, and I decided to experiment locally. I gathered advice as to the suitability of certain soil on the Sunday River, and of the climate, and the difficulty of securing skilled labour was eventually overcome. The size of the plants and of the leaves, and the quality of the tobacco, proved highly satisfactory, and the aroma and flavour were excellent.

The following year I extended operations to prove the profits of tobacco culture, with the result that the demand for the local-grown tobacco exceeded far the supply. Many farmers came to view the fields, and a number of them are planting this season, which is encouraging. I am now experimenting with Turkish cigar variety and Brazilian tobaccos. Unfortunately, however, skilled labour is wanting, which is proving a drawback and hardship. Fermentation and the curing of the leaves are imperfectly understood, and our workmen cannot grasp that successful culture lies in such apparently small matters as weeding and in the keeping of the soil loose, topping carefully and systematically, and in the gathering of the leaves separately (and ripe leaves only), and carefully conveying them to the drying sheds.

Cotton Culture.—Last year I planted the following kinds of cotton—Barbadoes, St. Vincent, Egyptian Abbassi, and American Rattler. The plants grew well and the bolls, with a fine fibre lint, were large and well developed. Cotton cultivation should be encouraged, and it is pleasing to find that the East London Chamber of Commerce is taking the matter in hand.

Castor Oil.—On the mines and elsewhere in the Union there is practically an unlimited demand for castor oil. To experiment with the cultivation of the castor bean followed naturally, and I planted the Italian and the colonial kinds. Both grew well and yielded beyond expectations. Under irrigation I feel sure nothing more profitable can be cultivated, but as such lands are limited and largely required for lucerne and cereal cultivation, I experimented under conditions approaching those of dry lands with satisfactory results. If dry, the first season might prove trying, but even under adverse conditions, its cultivation will pay from the first year; and as the castor plant or tree is perennial, unless too much exposed the first year or two to frost, I most strenuously advocate its cultivation on dry lands, that is, ground lying idle and useless at present, of which there are millions of acres. I also planted a variety which attains a height of upwards of ten feet with wide-spreading branches, strong enough to support a man's weight. It is, therefore, not difficult to grasp the rich harvest obtainable therefrom. Still our farmers shrug their shoulders and smile when urged to grow the castor bean. Yet ere very many more years have passed the castor bean, like lucerne, against which farmers exhibited bitter dislike, will be grown extensively, and prove a profitable branch of South African agriculture.

P. J. FOURIE.

Jansenville, August 5th, 1911.

GENERAL NOTES.

THE IMPORT TRADE OF MONASTIR.—The Italian Consul at Monastir, in a report to the Minister of Foreign Affairs at Rome, states that the value of the imports to that district during 1910 amounted to 9,091,300 francs (£363,652), of which other parts of Turkey contributed more than half, viz., to the value of 4,960,800 francs; Austria, 1,089,300 francs; Germany, 519,700 francs; Belgium, 508,000 francs; Great Britain, 466,000 francs, whilst the imports from Italy only amounted to 151,000 francs (£6,140) in value, or about one-sixtieth. The report, whilst showing that the imports are increasing, points out that manufacturers would do well to put themselves in direct communication with the local traders by sending out representatives. The present time is especially favourable for military outfitters, as Monastir is shortly to become the headquarters of an army corps. Italian flour of ordinary quality finds a ready market, and there is an increasing demand for Italian "Vermouth," "Fernet," and other liqueurs. The sale of chocolate might be considerably increased by judicious advertising. Knitted goods and hosiery, both cotton and wool, find a ready sale throughout the district, whilst chemical and pharmaceutical products are in demand. Amongst other goods may be mentioned leather, ready-made boots and shoes of medium quality, rope and twine, packing paper, earthenware and majolica of ordinary quality, thread and sewing-cotton on reel, cotton goods of every description, "cretonnes," flannels, etc.

COMMERCE OF ITALY.—During the first six months of the present year the total value of the foreign trade of Italy, as compared with that of the corresponding period last year, was as follows:—

	1910.—Lire.	1911.—Lire.	Increase.
Imports . . .	1,594,221,640	1,798,128,596	203,906,956
Exports . . .	1,009,316,418	1,029,722,794	20,406,376
	2,603,538,058	2,827,851,390	224,313,332
or £ sterling .	104,141,522	113,114,055	8,972,533

MEGASS AND BAMBOO PAPER IN TRINIDAD.—After much experimenting in Trinidad it is claimed that paper from megass (sugar-cane refuse) has been successfully manufactured, and that with further possible development the refuse of the cane, now used only for fuel, may be used in connection with bamboo fibre in the manufacture of a paper which, in quality and price, can command the market against any wood-paper now thereon. The quality of the fibre is obtained by combining the two fibres. Neither the cane-fibre nor that of the bamboo, used alone, will produce this paper. The proper combination of the two under conditions in which the experiments have been carried on, will alone give the desired result. The fibre of the bamboo is long and coarse, while that of the cane is short and soft, and in their combination the happy medium is said to have been found. It is said that no chemicals have been used in making the paper, and the difference in colour is produced by the addition of a little pigment to give the shade desired. The bamboo grows in large quantity in Trinidad, and the extent of the sugar industry is such that there would be no lack of the raw material.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

BREWING AND MODERN SCIENCE.

By Professor ADRIAN J. BROWN, F.R.S.

Lecture III.—Delivered February 20th, 1911.

THE MASHING PROCESS.

My last lecture was an attempt to describe the position of our present knowledge in connection with some of the complex biological problems which are associated with the germination of the barley corn and the production of malt. This evening I purpose to discuss certain problems associated with the brewer's mashing process.

The mashing process by which the brewer obtains his sweet wort from malt is very usually regarded as the commencement of brewing; but in reality the actions which take place in the brewer's mash-tub have their origin in the germination changes of the barley corn when it is on the malting floor, and may be looked at as a continuation of these changes. In the last lecture we saw how nature had provided the barley corn with a large store of starch and other suitable material as a food-supply for the embryo during its development. If germination of the corn proceeds unchecked, the whole of this food-supply is assimilated by the embryo after it has been transformed by the diastase and other enzymes of the corn into sugar and other soluble nutritive material. In the preparation of malt, however, germination changes in the barley corn are arrested by drying at a comparatively early stage, prior to the occurrence of any marked solution of the endosperm, but at a time when an accumulation of diastase and other enzymes has already taken place within the corn. Under these conditions the malted corn is potentially self-digestive, and when it is placed, as in the mashing process, under conditions favourable to the action of its contained enzymes, transformation of the endospermic food reserve into sugar and other soluble constituents takes place. So the production of the brewer's sweet wort is due to an artifice of man by means of which digestion of the starchy endosperm of the barley corn is made to take place in the mash-tub, instead of within the coverings of the germinating corn as designed by nature.

I have referred to the brewer's mashing process as an operation in which starch together with other solid constituents of the endosperm of the malted corn are digested, or transformed into soluble matter, by the secreted enzymes of the malt. Now, among all the changes which take place in the mash-tub, the one of prime importance to the brewer is the transformation of the starch of the malt into soluble constituents, for these soluble constituents constitute the main basis of the brewer's sweet wort, and the qualities of beer as a beverage are to a very large extent determined by their composition. It is easy to understand, therefore, that the chemistry of starch transformation is a subject of such fundamental importance in connection with the brewer's art that it is very desirable for me to refer to it in these lectures. I confess, however, that I approach the subject with great hesitation, and if it were possible I would gladly avoid it altogether. In the first place the great complexity of the subject, and the vast amount of work which has been done in connection with it, renders it impossible for

me to do it full justice in the time at my disposal, even if I dared venture to inflict details of investigations on my audience which are only suitable for specialists in carbo-hydrate chemistry; and, in the second place, the difficulties of handling the subject are enhanced by the knowledge that a militant spirit is apt to be called into vigorous existence when the nature of starch and its transformation products is discussed from any point of view. To navigate a suitable and safe course between Scylla and Charybdis is, I fear, beyond my powers, but under the stress of circumstances I feel compelled to make the attempt.

The birth of our modern views of the chemistry of starch and its transformation products dates from 1872, when Cornelius O'Sullivan made his noteworthy rediscovery of maltose,* and demonstrated that it was this sugar and not glucose which was formed during the transformation or hydrolysis of starch by diastase. Previous to this time the hydrolysis of starch by diastase was supposed to result in the formation of the sugar dextrose, and a gum-like body, dextrin, in some such manner as is represented by the following chemical expression

$$\underset{\text{Starch}}{2C_6H_{10}O_5} + H_2O = \underset{\text{Dextrose}}{C_6H_{12}O_6} + \underset{\text{Dextrin.}}{C_6H_{10}O_5}$$

Even as late as 1873, when Dr. Graham delivered his course of lectures on brewing, he was not in possession of very full knowledge concerning O'Sullivan's discoveries, and for the most part Graham's treatment of the subject of starch transformation in the mash-tub was based on the incorrect assumption that dextrose and dextrin were the products formed.

C. O'Sullivan's discovery that maltose, not dextrose, was the sugar produced during starch hydrolysis by diastase exerted a profound influence on the progress of knowledge in connection with starch transformation. Older conceptions were modified or swept away, and a new field of work was opened up for investigation which promised results of the greatest importance for science and technology. But this field of work, so attractive in its possibilities, proved much more complex than it originally appeared when O'Sullivan commenced to study it, and for the past thirty-eight years it has provided chemists with problems of unsurpassed difficulty. Until we look into the history of the subject, it is difficult to realise what a vast amount of work has been carried on in connection with it from the time of O'Sullivan's early work until the present day. Among the chief investigators of the subject, commencing with O'Sullivan, we find such names as Musculus and Grüber, Brown and Heron, C. J. Lintner, Brown and Morris, Ling and Baker, Syniewski, Brown and Millar, Ling and Davis, Ford, Fernbach, and Maquenne, all of whom have contributed largely to the advance of knowledge of the subject. But notwithstanding the vast amount of work which has been carried out by these and other investigators, essential points in connection with the subject are still in dispute, and at the present time there is no general agreement to accept any one of the views which have been advanced to explain the constitution of the starch molecule and the manner in which it breaks down under the influence of diastase. It is impossible, under these conditions, to review within the time at my disposal the position of our knowledge of this subject in all the various aspects in which it has been presented by its numerous investigators. I propose, therefore, to confine my remarks to a few only of the many views which have been advanced to explain the subject, selecting for this purpose those which appear to follow each other in an ordered sequence and to terminate in a more or less definite conclusion.

In the first place, I propose to refer to C. O'Sullivan's earlier investigations, which unquestionably constitute the foundation on which all subsequent work on the transformation of starch by diastase has been based.

From the result of O'Sullivan's early investigations, which demonstrated that maltose, not dextrose, was the sugar formed during the transformation of starch by diastase, this author formed the opinion that starch, when hydrolysed by diastase, was dissociated into a mixture of maltose and a gum, dextrin, and that these two carbo-hydrates constituted the sole products of the change. Under these conditions it appeared possible, therefore, to represent the general character of the action of diastase on starch by some such chemical expression as the following

$$\underset{\text{Starch}}{3C_6H_{10}O_5} + H_2O = \underset{\text{Maltose}}{C_{12}H_{22}O_{11}} + \underset{\text{Dextrin.}}{C_6H_{10}O_5}$$

Subsequent investigation of the subject by O'Sullivan himself* not only confirmed this opinion, but further demonstrated the highly important fact that the temperature at which the conversion of starch proceeds exercises a very great influence on the character of the

* *Journal of the Chemical Society*, 1872, Vol. XXV., p. 579.

* *Journal of the Chemical Society*, 1876, Vol. II., p. 125.

changes which take place. It had long been known that when the temperature during starch conversion much exceeded 70° C. (158° F.) the hydrolysing action of diastase on starch was arrested; but O'Sullivan's investigations demonstrated that at varying temperatures below the one at which diastase ceases to be active, very marked differences are observed in the relative quantities of maltose and dextrin formed. For instance, O'Sullivan showed that when hydrolysis of starch is effected by malt diastase at any temperature below 63° C. (145° F.), the conversion products possess an optical rotatory power and reducing power approximating closely to those of a mixture of maltose and dextrin in the proportions of 68 to 32. This conversion change was assumed by O'Sullivan to be represented by the following equation

A.—

$$\underset{\text{Starch}}{6C_{12}H_{20}O_{10}} + 4H_2O = \underset{\text{Maltose}}{4C_{12}H_{22}O_{11}} + \underset{\text{Dextrin.}}{2C_{12}H_{20}O_{10}}$$

Again, O'Sullivan showed that if a starch conversion was carried on at any temperature between 64° C. and 68° C. (147°–154° F.) the products of conversion exhibit an optical rotatory power and reducing power closely approximating to those of a mixture of maltose and dextrin in the proportions of 35 to 65. This change was supposed to be represented by the equation

B.—

$$6C_{12}H_{20}O_{10} + 2H_2O = 2C_{12}H_{22}O_{11} + 4C_{12}H_{20}O_{10}$$

O'Sullivan further demonstrated, when a conversion was carried on between the temperatures of 68° C. (154° F.) and 70° C. (158° F.)—the point at which the activity of diastase tends to be destroyed—that the optical rotatory power and reducing power of the transformation products agree closely with those of a mixture of maltose and dextrin in the proportions of 17 to 83. This change was assumed to be represented by the equation

C.—

$$6C_{12}H_{20}O_{10} + H_2O = C_{12}H_{22}O_{11} + 5C_{12}H_{20}O_{10}.$$

These early investigations of O'Sullivan appeared to indicate, therefore, that the transformation of starch by diastase into maltose and dextrin took place in three definite changes, the character of which was determined by temperature and represented by the equations *A. B.* and *C.* given above.

But when this subject was reinvestigated by H. Brown and Heron in 1879, these chemists were unable to confirm the definite character of O'Sullivan's three equations, and the results of their investigations led them to regard the transformation of starch from a different point of view to the one advanced by O'Sullivan. O'Sullivan supposed that starch was hydrolysed by diastase to maltose and a dextrin possessing a definite and simple structure, the relative amounts of maltose and dextrin being determined by the temperature at which transformation takes place. Brown and Heron, in agreement with a view previously advanced by Musculus and Grüber, were led to regard starch as a carbo-hydrate possessing a very large molecule, which did not, as O'Sullivan supposed, break down at once under the influence of diastase into maltose and a definite dextrin, but into maltose through a series of dextrins of gradually decreasing complexity. They conceived the idea that the molecule of soluble starch was represented by the formula $10(C_{12}H_{20}O_{10})$. The first step in the breaking down of this complex molecule was supposed to consist in the hydration of one of its $C_{12}H_{20}O_{10}$ groups with the formation of a molecule of maltose, the remaining nine $C_{12}H_{20}O_{10}$ groups constituting the first complex dextrin molecule, named erythrodextrin *a*, thus

I.—

$$\underset{\text{Starch}}{10(C_{12}H_{20}O_{10})} + H_2O = \underset{\text{Maltose}}{C_{12}H_{22}O_{11}} + \underset{\text{Erythrodextrin } a.}{9(C_{12}H_{20}O_{10})}$$

The molecule of erythrodextrin *a* was next supposed to be hydrolysed in the following manner

II.—

$$\underset{\text{Erythrodextrin } a}{9(C_{12}H_{20}O_{10})} + H_2O = C_{12}H_{22}O_{11} + \underset{\text{Erythrodextrin } \beta.}{8(C_{12}H_{20}O_{10})}$$

The next stage thus

III.—

$$\underset{\text{Erythrodextrin } \beta.}{8(C_{12}H_{20}O_{10})} + H_2O = C_{12}H_{22}O_{11} + \underset{\text{Achrodextrin } a.}{7(C_{12}H_{20}O_{10})}$$

Hydration was assumed to proceed in this manner through ten stages, until finally the last $C_{12}H_{20}O_{10}$ group of the original starch molecule was transformed into maltose.

The sequence in which these ten changes was supposed to proceed is represented in the following equation

$$\begin{array}{l} \\ 10(C_{12}H_{20}O_{10}) + \\ \text{Soluble starch} \\ \text{molecule.} \end{array} \left\{ \begin{array}{rcl} & \text{Dextrins} & \text{Maltose.} \\ 1H_2O = & 9(C_{12}H_{20}O_{10}) + & C_{12}H_{22}O_{11} \\ 2H_2O = & 8(C_{12}H_{20}O_{10}) + & 2C_{12}H_{22}O_{11} \\ 3H_2O = & 7(C_{12}H_{20}O_{10}) + & 3C_{12}H_{22}O_{11} \\ 4H_2O = & 6(C_{12}H_{20}O_{10}) + & 4C_{12}H_{22}O_{11} \\ 5H_2O = & 5(C_{12}H_{20}O_{10}) + & 5C_{12}H_{22}O_{11} \\ 6H_2O = & 4(C_{12}H_{20}O_{10}) + & 6C_{12}H_{22}O_{11} \\ 7H_2O = & 3(C_{12}H_{20}O_{10}) + & 7C_{12}H_{22}O_{11} \\ 8H_2O = & 2(C_{12}H_{20}O_{10}) + & 8C_{12}H_{22}O_{11} \\ 9H_2O = & 1(C_{12}H_{20}O_{10}) + & 9C_{12}H_{22}O_{11} \\ 10H_2O = & — & 10C_{12}H_{22}O_{11} \end{array} \right.$$

But the hypothesis of H. Brown and Heron regarding the hydrolysis of starch to which I have just referred, was subsequently modified very considerably by researches on the same subject by H. Brown and Morris.*

One of the marked features noticeable when laboratory starch conversions are conducted at any temperature favourable to the full activity of diastase, is the tendency they possess of coming rapidly to a state of quasi-equilibrium when the products of change are represented by the equation

$$\underset{\text{Starch}}{10(C_{12}H_{20}O_{10})} + 8H_2O = \underset{\text{Dextrin}}{2C_{12}H_{20}O_{10}} + \underset{\text{Maltose}}{8C_{12}H_{22}O_{11}}$$

which is the No. 8 equation of Brown and Heron (see above). Transformation of starch through the different higher dextrins of Brown and Heron appears to take place with very considerable rapidity down to this stage, and then a dextrin seems to be formed which is hydrolysable by diastase only with extreme slowness. The strong resistance of the dextrin of the No. 8 equation to hydration appeared to indicate that there must be some marked difference in the constitution of this dextrin to that of the dextrins of the higher conversions, and Brown and Morris made a special investigation of this point by separating the dextrins of different equations and examining them. The stable dextrin of the No. 8 equation appeared to possess a definite optical rotatory power, and no reducing power; on the other hand, of the higher dextrins examined, all possessed some reducing power and an optical rotatory power which was less than that of the stable dextrin of the No. 8 equation. Further, it was found that if the higher dextrins were acted on by diastase they were very rapidly hydrolysed to a mixture of maltose and the same non-reducing stable dextrin as that of the No. 8 equation.

As it appeared, from the results of Brown and Morris's investigations, that the stable dextrin of the No. 8 equation differed in a marked manner from the higher dextrins of Brown and Heron, Brown and Morris were led to advance a hypothesis regarding the nature of starch transformation which differed very materially from that of Brown and Heron.

In the change represented by the No. 8 equation it will be observed that one-fifth of the starch concerned in the change is converted into stable dextrin, thus

$$\underset{\text{Starch}}{10(C_{12}H_{20}O_{10})} + 8H_2O = \underset{\text{Stable Dextrin}}{2C_{12}H_{20}O_{10}} + \underset{\text{Maltose.}}{8C_{12}H_{22}O_{11}}$$

* *Journal of the Chemical Society*, 1885, p. 527; 1888, p. 610; 1889, p. 449; 1889, p. 462.

Under these conditions Brown and Morris were led to regard the molecule of starch as being composed not of ten groups of $C_{12}H_{20}O_{10}$, as suggested by Brown and Heron, but of five such groups, four of which were similar in character and were readily hydrolysed to maltose by diastase, the remaining fifth group of a more resistant character constituting stable dextrin. According to this hypothesis, starch transformation at a temperature of 60° C. or below may be represented by the following equation

$$5(C_{12}H_{20}O_{10}) + 4H_2O = 4C_{12}H_{22}O_{11} + (C_{12}H_{20}O_{10}).$$

But it will be noticed that this equation does not of necessity indicate the magnitude of the starch molecule which takes part in the transformation. It is evident, however, from the equation that the molecule of stable dextrin must be one-fifth the size of the starch molecule. What, therefore, is the size of the stable dextrin molecule represented in the equation by the empirical formula $(C_{12}H_{20}O_{10})$? From Brown and Morris's investigations, and subsequently from those of Brown and Millar, there is reason to believe that the molecule of stable dextrin may be represented by the formula $20(C_{12}H_{20}O_{10})$. Granting this, the molecule of soluble starch taking part in a starch transformation by diastase cannot be less than $100(C_{12}H_{20}O_{10})$. Consequently, according to the hypothesis of Brown and Morris, the probable molecular expression for a transformation of starch according with the No. 8 equation is

$$\left.\begin{matrix}(C_{12}H_{20}O_{10})_{20}\\(C_{12}H_{20}O_{10})_{20}\\(C_{12}H_{20}O_{10})_{20}\\(C_{12}H_{20}O_{10})_{20}\\(C_{12}H_{20}O_{10})_{20}\end{matrix}\right\}\begin{matrix}+ 80H_2O\\ = (C_{12}H_{20}O_{10})_{20} + 80C_{12}H_{22}O_{11}.\end{matrix}$$

According to this conception, four of the $(C_{12}H_{20}O_{10})_{20}$ groups in the starch molecule are of a similar nature and are readily hydrolysed to maltose; but the fifth group is of a different nature and splits off during hydrolysis to form the stable dextrin of the No. 8 equation.*

So far no attempt has been made to explain

* It will be noticed that the conception that the starch molecule is not less than $100(C_{12}H_{20}O_{10})$ depends on the accuracy of the view that the molecule of dextrin is $20(C_{12}H_{20}O_{10})$. Brown and Morris arrived at the conclusion that the molecule was of this size from the freezing-point method, and Brown and Millar arrived at a similar conclusion from analysis of the calcium salt of dextrinic acid—an acid formed by oxidation of the so-called "stable dextrin." The reliability of the methods employed by these investigators has been questioned; but so far, no direct experimental evidence has been brought forward which tends to invalidate their conclusion.

by means of Brown and Morris's hypothesis the nature of the reducing dextrins of high type which were shown by Brown and Heron to exist in the earlier stages of a starch transformation. The origin of the reducing dextrins, according to Brown and Morris, is in the four groups of the starch molecule which are finally converted into maltose in an unrestricted conversion. These groups, during hydration, are supposed to break down gradually into maltose through a varying series of reducing dextrins, or so-called malto-dextrins, the molecules of which appear to consist of maltose and dextrin in a somewhat loose state of combination. The manner in which each of the four completely hydrolysable groups of the starch molecule breaks down through a series of malto-dextrins of gradually increasing reducing power and decreasing optical activity is indicated by Brown and Morris in the following way

$$(C_{12}H_{20}O_{10})_{20} + H_2O = \begin{cases} (C_{12}H_{22}O_{11}) \\ (C_{12}H_{20}O_{10})_{19} \end{cases}$$

$$= \text{Malto-dextrin with ratio } \frac{1 \text{ Maltose}}{19 \text{ Dextrin}}.$$

$$(C_{12}H_{20}O_{10})_{20} + 10H_2O = \begin{cases} (C_{12}H_{22}O_{11})_{10} \\ (C_{12}H_{20}O_{10})_{10} \end{cases}$$

$$= \text{Malto-dextrin with ratio } \frac{10 \text{ Maltose}}{10 \text{ Dextrin}}.$$

$$(C_{12}H_{20}O_{10})_{20} + 19H_2O = \begin{cases} (C_{12}H_{22}O_{11})_{19} \\ (C_{12}H_{20}O_{10}) \end{cases}$$

$$= \text{Malto-dextrin with ratio } \frac{19 \text{ Maltose}}{1 \text{ Dextrin}}.$$

In a starch conversion restricted by heat or other condition, it is assumed that any of these malto-dextrins, or mixtures of a number of them, may be obtained.

The first stage in the hydrolysis of the starch molecule may perhaps be represented by the following equation

$$\left.\begin{matrix} (C_{12}H_{20}O_{10})_{20} \\ (C_{12}H_{20}O_{10})_{20} \\ (C_{12}H_{20}O_{10})_{20} \\ (C_{12}H_{20}O_{10})_{20} \\ (C_{12}H_{20}O_{10})_{20} \end{matrix}\right\} + 4H_2O$$

$$= \underset{\text{Stable dextrin}}{(C_{12}H_{20}O_{10})_{20}} + 4 \underset{\substack{\text{Highest type} \\ \text{Malto-dextrin,}}}{\begin{cases} (C_{12}H_{22}O_{11}) \\ (C_{12}H_{20}O_{10})_{19} \end{cases}}$$

in which the molecule of starch is dissociated into its five main groups; the fifth group, which strongly resists hydrolysis, is split off to form the stable dextrin of the No. 8 equation. The other four groups are each hydrolysed to the highest type of malto-dextrin containing maltose and dextrin in the proportion of 1 maltose to 19 dextrin.

Subsequently, as hydration proceeds, the stable dextrin remains unchanged, but the malto-dextrin molecules are further hydrolysed—some may be completely hydrolysed to free maltose, and others to lower-type malto-dextrins. If hydrolysis is arrested by high temperature, or other influence, some such position may be reached as is indicated by the following equation

$$\left.\begin{matrix} (C_{12}H_{20}O_{10})_{20} \\ (C_{12}H_{20}O_{10})_{20} \\ (C_{12}H_{20}O_{10})_{20} \\ (C_{12}H_{20}O_{10})_{20} \\ (C_{12}H_{20}O_{10})_{20} \end{matrix}\right\} + 60H_2O$$

$$= \underset{\text{Stable dextrin}}{(C_{12}H_{20}O_{10})_{20}} + 2 \underset{\text{Malto-dextrin}}{\begin{cases} (C_{12}H_{22}O_{11})_{10} \\ (C_{12}H_{20}O_{10})_{10} \end{cases}} + \underset{\text{Free maltose.}}{40C_{12}H_{22}O_{11}}$$

This equation should be looked at, however, as illustrating only the general character of change during restricted conversion. It is probable, according to Brown and Morris, that the malto-dextrins existing at any time during starch hydrolysis, are mixtures of various types—not one type, such as is indicated in the above equation.

A point of much technical importance which remains for discussion concerns the properties of the malto-dextrins, or reducing dextrins formed during starch hydrolysis. These bodies, although they possess an optical rotatory power and reducing power closely resembling those of mixtures of maltose and stable dextrin and were considered to be mixtures in the earlier days of investigation, have been shown by Brown and Morris to be definite compounds. For instance, when their characteristics were compared with those of a mixture of maltose and stable dextrin, such as is obtained by the unrestricted conversion of starch to the No. 8 equation, it was found that primary yeast readily fermented the whole of the free maltose which was present in the mixed conversion products and left the stable dextrin unaltered; on the other hand, the malto-dextrins of a restricted starch conversion were found to be unfermentable by the same type of yeast. Again, it was found that fractional precipitation with alcohol effected a separation of dextrin from maltose when the two existed together in solution as a mixture; but no fractionation of dextrin from maltose could be effected by similar treatment of solutions of malto-dextrins. A very marked difference was also observed in the behaviour of malto-dextrins and the mixed starch conversion products of the No. 8 equation when under the influence of diastase at temperatures below

60° C. (140° F.). It was found that no appreciable change took place within a limited time in the case of mixtures of dextrin and maltose, but malto-dextrins were very rapidly hydrolysed to pure maltose. The latter result, of course, should be observed if—according to the Brown and Morris hypothesis—malto-dextrins represent partially hydrolysed portions of the four groupings of the starch molecule which are so readily attacked during an unrestricted starch transformation.

From a technical point of view, the unfermentable nature of the malto-dextrins, or reducing dextrins, assumed by the Brown and Morris hypothesis to be present among the products of a restricted starch conversion, is a matter of great importance. If the starch transformation products constituting the greater part of the soluble matter of the brewer's malt wort consisted of maltose and stable dextrin only, the whole of the maltose would be transformed into alcohol and carbon dioxide during fermentation in the brewery, and the fermented liquid would be highly alcoholic and very "thin" in palate flavour owing to complete removal of the sweet "body-giving" constituents originally contained in it. Moreover, when the fermented wort was placed in cask it would contain no carbohydrate matter suitable for generating the secondary fermentation changes which are so essential for the proper "conditioning" of beer, and it would remain a thin, "flat" liquid, very different from the full-drinking beverage charged with carbon dioxide which we recognise as beer. The brewer knows, however, that during the primary fermentation of his malt wort in the brewery the whole of the sweet-flavoured constituents of his wort does not ferment away, and that some portion is left which gives sweetness and "palate fulness" to his beer. He knows, moreover, that some fermentable matter still exists in his finished beer—not readily fermentable matter, or it would have fermented away during primary fermentation in the brewery—but matter capable of sustaining a slow secondary fermentation in cask or bottle for months, or may be for years.

Both of these phenomena of such ruling importance in the brewing industry are explained if we recognise that carbohydrates are present in the brewer's wort which possess similar characteristics to those of the malto-dextrins, or reducing dextrins, indicated by Brown and Morris's researches. We have already seen that malto-dextrins are unfermentable by primary yeast, hence their presence in a brewer's wort explains the persistence of the sweet-flavoured constituents noticeable in the wort after it has undergone primary fermentation and has been converted into beer in the brewery. The highly important influence of the malto-dextrins in establishing the secondary conditioning of beer is also explained by the knowledge that, although malto-dextrins are not fermentable during primary fermentation in the brewery, they are slowly fermented by the so-called "secondary" yeast forms which develop in beer when in cask or bottle. Yeasts of this type appear to generate enzymes capable of very slowly hydrolysing the complex malto-dextrin molecule to free maltose, the sugar liberated being subsequently decomposed by the yeast into carbon dioxide and alcohol, thus giving rise to the phenomenon of "secondary fermentation," or "conditioning" of beer.

With regard to the presence of malto-dextrins in the brewer's wort, it will be noticed that the heat at which the brewer conducts his mashing operations approximates closely to 66° C. (151° F.), a temperature which restricts hydrolysis of starch by diastase and consequently favours the production of malto-dextrins.

Subsequent to Brown and Morris's investigations, the results of which I have endeavoured to explain, Brown, working in conjunction with Millar, conducted further researches,* which led to a slight modification of the view of Brown and Morris regarding the constitution of the starch molecule. The so-called stable dextrin of the No. 8 equation, which is supposed to be derived from one of the five groupings of the starch molecule, was regarded by Brown and Morris as a non-reducing dextrin containing twenty so-called "maltase" groups

$$(C_{12}H_{20}O_{10})_{20}$$

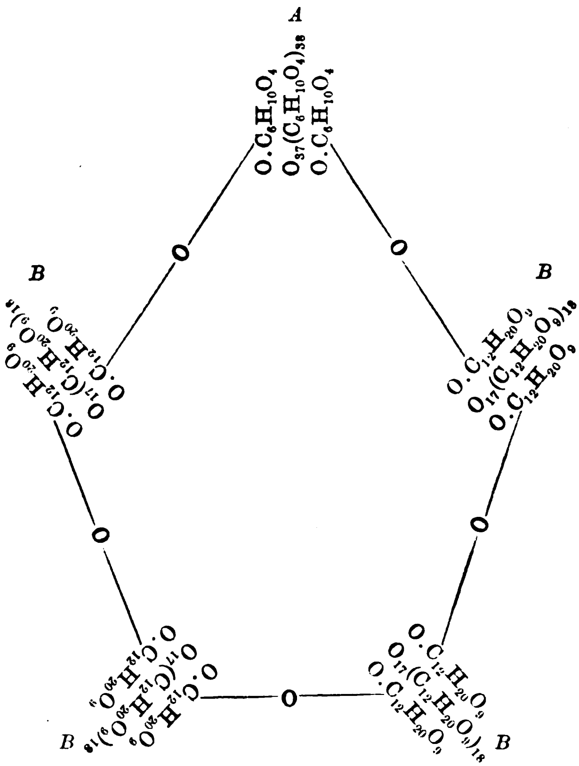
Non-reducing dextrin.

But Brown and Millar, from the results of further work, satisfied themselves that "stable" dextrin possesses a small reducing power due to the existence in its molecule of a $C_6H_{12}O_6$ (dextrose) group. Under these conditions they could no longer regard the stable grouping of the starch molecule, which yields dextrin, as composed of twenty $(C_{12}H_{20}O_{10})$ groups, but as containing thirty-nine $C_6H_{10}O_5$ groups and one $C_6H_{12}O_6$ group as represented in the following formula

$$\begin{cases} (C_6H_{10}O_5)_{39} \\ C_6H_{12}O_6 \end{cases}$$

* *Journal of the Chemical Society*, 1899, Vol. LXXV., p. 315.

The final picture of the possible constitutional formula of the molecule of soluble starch proposed by Brown and Millar is given below.



A. Dextran residue.
B. Maltan residues.

At the commencement of this lecture I stated that it was impossible within the brief time at my disposal to discuss thoroughly the progress of knowledge regarding our modern knowledge of starch transformation owing to the complexity of the subject, and the overwhelming amount of work which has been done in connection with it. In order to meet this somewhat impossible situation as well as I could, I proposed to refer to one line of investigation only which exhibits consistent progress towards the foundation of a definite hypothesis. It was for this reason I have selected O'Sullivan's original work as the foundation of my remarks, and have followed by endeavouring to show how the final hypothesis of Brown, Morris and Millar has developed from it. I regret that through treating my subject in this way I have not been able to refer to the work of many notable investigators, such as C. Lintner and Syniewski—or even to the work of Maquenne and Roux, Fernbach, and others of the French school, which is still proceeding and which gives promise of most important results—but, if I had attempted to do otherwise, I felt it must infallibly end in confusing my audience, whom I cannot altogether regard as specialists in carbohydrate chemistry. As it is, owing to the complex nature of the chemistry of my subject, I fear my remarks must have proved somewhat difficult to follow.

The view of Brown, Morris and Millar regarding the constitution of the starch molecule and the manner in which it is transformed when under the influence of diastase is not regarded favourably by all starch specialists—in fact, it appears to exert a peculiarly irritating effect on the minds of some; but, on the other hand, although the view has been very severely criticised from time to time, I am not aware of the existence of any experimental evidence which has, as yet, seriously questioned its validity. Moreover, no other view advanced at present appears capable of explaining so much—and this is a matter of prime importance with regard to its value as a working hypothesis. Nevertheless, it is well to bear in mind the great difficulties which surround such an investigation as that of the action of diastase on starch, and the probability of future work leading to some modification of any view yet advanced.

There are very many points in connection with diastase and enzymes of a kindred nature present in malt about which much uncertainty exists. Do several forms of diastase exist in malt, contributing to the different stages in the degradation of the starch molecule which have been observed by so many investigators? From the influence of heat on the products of starch transformation, and from other evidence brought forward by Maquenne and Roux, it is probable that such may be the case, but at present we are waiting for solid proof that it is so. Again, what is the nature and *rôle* of the liquefying enzyme which plays such an important part in the modification of starch paste, and in the solution of starch in the brewer's mash-tub? Probably it is a different enzyme from the ordinary diastase of transformation, but there is much in connection with this question which is of great technical and

scientific importance and which requires further investigation.

Consideration of such questions as these brings forward another point of great importance in brewing technology. We have seen that the hypothesis of Brown, Morris and Millar appears to be in agreement with the phenomena observed during the hydrolysis of starch by diastase under laboratory conditions when the enzyme in comparatively small amount acts on starch paste, or soluble starch. Are the results observed during starch conversion in the brewer's mash-tub, when diastase in very large amount acts on the starch granules of malt, also in agreement with Brown and Morris's hypothesis? Viewed broadly, they present a general appearance of agreement, but looked at closely they are usually found to vary materially from those which Brown and Morris's hypothesis would lead us to expect.

Temperature appears to influence the nature of starch transformation by diastase to a much greater extent when the action proceeds under laboratory conditions, than when it takes place in the brewer's mash-tub, and it is by no means safe to assume that the results obtained at any particular temperature in the mash-tub will be similar to those obtained at the same temperature in a laboratory starch transformation. This does not, however, of necessity throw doubt on the soundness of Brown and Morris's hypothesis. This hypothesis is founded on the results of laboratory experiments in which the conditions of experiment were kept as free as possible from complicating factors. The conclusions derived from experiments such as these may be correct, and yet they may not be able to explain the nature of starch transformation in the mash-tub, owing to other actions taking place during the brewer's mashing process which obscure, or modify, the actions observed in a laboratory starch transformation.

Brief consideration of the conditions ruling during mash-tub conversion will show how complex the conditions are as compared with those of an ordinary laboratory conversion. Action in the mash-tub commences on solid starch granules—not on starch paste or a solution of soluble starch, as in a laboratory starch conversion—and it is initiated by the activity of one or more enzymes of which we know little, which assist in gelatinising and liquefying the starch. Following immediately on these changes, the soluble starch is brought under the influence of a very large excess of diastase derived from the malt, a condition very different from that of an ordinary laboratory starch conversion in which only a limited amount of diastase is employed. Moreover, during conversion changes in the mash-tub another difference of condition exists, which probably exerts an important influence on the nature of the occurring starch transformation. This consists in the presence of a large amount of soluble and insoluble material of very various nature derived from the malt, and it is well known how susceptible the actions of diastase and other enzymes are to influences such as these. Therefore, under the complex conditions of starch transformation in the brewer's mash-tub referred to, it is reasonable to expect that the character of the changes will differ from those taking place under similar conditions of temperature in a simple laboratory starch transformation.

Our knowledge of starch and its conversion changes has undoubtedly increased very much during the past thirty-seven years, but, notwithstanding the vast amount of work which has been done in connection with these subjects, we are not yet masters of the complex changes which proceed during starch transformation in the mash-tub. It is disappointing to be compelled to say this, but it is highly desirable that the fact should be recognised in order to encourage future investigation in a direction of the very greatest importance to the brewer, the distiller, and the vinegar-maker. If the subject of starch, which I have discussed this evening with some trepidation, had not become such a very controversial one, we should have proceeded faster and further in our search after knowledge. There is no doubt a humorous side to starch polemics which some of us value, but we could well afford to sacrifice this for the advantages of calmer discussion and more rapid progress.

ECONOMIC ASPECTS OF THE INTRODUCTION AND ESTABLISHMENT OF A BRITISH BEET-SUGAR INDUSTRY.*

Great Britain is the greatest sugar consumer in the world. We imported last year (1910) 1,745,129 tons of sugar, of which 1,303,319 tons were beet-sugar, and 441,810 tons cane-sugar. We sent abroad last year £25,307,214 for sugar. The question may well be asked whether we can keep this immense amount of money in our country by

* Abstract of a paper read by Mr. Sigismund Stein before the Section of Economic Science and Statistics of the British Association at Portsmouth, 1911.

producing the sugar ourselves. England distinguishes herself by being the only country in Europe which does not produce a single ounce of sugar herself. I have proved by over four thousand sugar-beet growing experiments, conducted in practically every county in the United Kingdom in the last twenty consecutive years, that we can successfully grow sugar-beet in these islands. The beet cultivation in Germany brought an increase on the yield of all crops. The beet culture forced the farmer to adopt very deep ploughing, along with scientific farming, and to proper treatment of the soil both chemically and physically. The ingenuity of the agricultural engineer invented new implements and machinery for this new departure in agriculture. The by-products and residue of the beet-sugar industry, called beet-pulp or "slices," are a very valuable cattle-food, by which the number of cattle could easily be increased, also the fattening of cattle fostered.

In Europe alone fifty million tons of sugar beetroot are cropped per year. Out of this vast quantity twenty-five million tons of sugar-beet pulp are produced, which are all used for cattle-feeding. This enormous quantity of cattle-food has been the means of considerably increasing the number of cattle on the Continent. England has entirely given herself up to manufacture and neglected agriculture, while Continental countries like Germany, where industry and manufacture have increased and improved at the same pace as ours, have not neglected agriculture. The question of employment is at the present moment a very pressing problem indeed. The 1,065,645 people in the United Kingdom who are under poor relief (1910), the many thousands of men and women we find in large towns and cities without employment, can be well occupied by the introduction of sugar-beet cultivation. If we introduce this gigantic industry into this country we would employ over 160,000 men in our sugar factories, about 200,000 men would find employment in the trades that work in connection with the sugar industry, and another 240,000 men would find additional employment in the fields. Taking it all round, by the work provided by the introduction of the beet-sugar industry, 600,000 men would find employment, representing 450,000 families, which at four per family would mean that 1,800,000, equal to 4 per cent. of the whole population, would be interested in the beet-sugar industry. Our position in the world depends upon maintaining a large rural population. We all read the sore and disquieting accounts of the depopulation of different districts in our islands. This ever-increasing exodus, which robs the country of the best healthy working men and women and a sturdy agricultural population and drives them into other countries, where they find more favourable economic conditions, and where they work in competition against us, could be stopped. The sugar-beet is most admirably adapted for small holdings. No other crop is so suitable, because sugar-beet can be grown year after year on the same land or with rotation.

To cover our demand for sugar we require five hundred factories to supply us with sugar, each factory would cost £80,000, so that £40,000,000 might be safely and profitably invested at home. The £25,000,000 sterling we send year by year to foreign countries would remain here, increase our wealth, benefit British agriculture, British trade and commerce, and British capital and labour. The high dividends paid during the last years by most Continental beet-sugar factories show the profitability of this industry. Our export of capital has already reached excessive dimensions. To produce all the sugar we consume we would require about a million acres to be cultivated with beet, which we could easily reclaim from the land that went out of cultivation during the last decade. In the progress of economic thought and study, and mainly through the efforts and zeal of practical British economists, the bounties which have been a menace for over thirty years have been abolished since September 1st, 1903. With the introduction of the beet-sugar industry there would go hand in hand the creation of the sugar-engineering industry and the agricultural-implement industry. To give an example of what would be required if we produced all the sugar we consume, I may mention that twelve million tons of beetroot would be necessary, one million tons of coal, 600,000 tons of limestone, 70,000 tons of coke, twenty million bags, four million cases, and an immense quantity of other materials.

SMOKE ABATEMENT: THE POSSIBILITY OF FIXING A NEW STANDARD OF SMOKE EMISSION FROM FACTORY CHIMNEYS.*

From the point of view of smoke emission the present position of the manufacturer who burns bituminous coal in his furnace is that, while he knows dense smoke to be unnecessary and wasteful, entire absence of smoke is practically impossible to attain under working conditions. The question, therefore, is, What is the least amount of smoke such a manufacturer might be asked to limit himself to?

The present legal standard of "black smoke in sufficient quantity to be a nuisance" is admittedly unsatisfactory, as black smoke is a thing rarely if ever seen; also, the blackness alone is no measure of the amount of pollution nor even of the amount of soot per ton of coal burnt. The present standard is therefore out of date. Meanwhile the public have to breathe polluted air, to suffer in health and pocket, have their buildings injured and disfigured, and their sunshine cut off.

A sound standard of maximum allowable amount

* Abstract of a paper read by Dr. J. S. Owens before the Engineering Section of the British Association at Portsmouth, 1911.

of smoke should be fixed and enforced. Two questions must be answered before such a standard can be fixed: (1) What is the best and most practicable method of measuring smoke? (2) Having decided on (1), what is a fair maximum of smoke emission to fix, as measured by (1)?

To answer the first question we must decide exactly *what* we are to measure. We may set ourselves to find out: (1) The total quantity of soot emitted in a given time; (2) the weight of soot emitted as a percentage of fuel burnt; (3) the density or weight of soot per unit volume of flue gas; (4) the ratio only of density to a standard; (5) the colour; (6) the opacity or blackness.

In deciding the method of measuring we must keep in view: (*a*) Fair comparison between chimney and chimney or with standard; (*b*) ease of application and simplicity; (*c*) reasonable accuracy; (*d*) the smoke must be measured from outside factory; (*e*) the method must be capable of use by a single observer.

The standard suggested is one of *maximum density for maximum time of emission.* By density is meant amount of soot per unit volume of flue gas. A smoke of great density would be permitted for a short time only, whereas one of less density might be permitted for a longer time.

The method of measuring the density suggested is by matching the opacity of the smoke to that of calibrated smoked glasses, each glass representing a certain density of smoke in a column of unit thickness. The final figure for comparison is obtained by dividing the density represented by the glass by the diameter of the chimney. By careful construction and the elimination of certain errors, an instrument can thus be made to give a fair basis of comparison with a standard density. The author has devised and experimented with an instrument of this type, with promising results. Certain objections will always remain to such a method of measuring, but the author believes that it is only along such lines that the necessary conditions can be fulfilled.

The Alkalies Act of 1906 fixes a standard maximum of one-fifth of a grain of muriatic acid per cubic foot in smoke or noxious fumes, and it appears that the time has arrived when the soot from furnaces should be dealt with on similar lines, modified to suit the case.

THE MANUFACTURE OF ARTIFICIAL EYES.

How such defects as the loss of an eye were remedied by the various nations in earlier years is difficult to imagine, for it appears that the first reliable report on the subject is given by the French surgeon Ambroise Paré in 1560, although a few unauthenticated reports date as far back as the Middle Ages. Two kinds of artificial eyes were known to Ambroise Paré—the ekblepharos and the hypoblepharos. The ekblepharos was made by painting the eye and all the surrounding parts as far as the brows on a plate, which was placed in front of the eye-socket, and held in position by a string tied over the head. The hypoblepharos was used in a manner similar to that of to-day, being put behind the eyelid, in the eye-socket itself, and was composed of a metal shell of copper, silver or gold, covered with enamel and glass fusions. The United States Consul-General of Coburg, who has recently reported to his Government on this subject, says that it is thought that Augsburg was the source of the enamelled shells, whence the art was taken to France, and as German art industries were ruined in the Thirty Years' War, Paris became the centre of the artificial eye industry. There are still opticians in Germany who advertise their eyes as "finest Paris eyes," although they are marked with German marks; but no less than 80 per cent. of the eyes now used in Paris, and the rest of France, are said to come from Germany. It was only at the close of the eighteenth century that these artificial eyes really became of practical use, it being then found possible to do away with the metal shell altogether and employ only enamel and glass. It is known that in the middle of the nineteenth century eyes were made by enamellers in Dresden, Prague, London and Stockholm, and in Thuringia. The Thuringian makers differed widely from the others in that they were not enamellers but glass-blowers, working in connection with the porcelain-painting industry, whose endless and untiring experiments resulted in the discovery of an ideal material, cryolite glass, the use of which led to a new technique in eye manufacture. At times, attempts have been made to replace the breakable glass by vulcanite or celluloid, but such efforts have long since been given up as useless. The fragility of artificial glass eyes, and their sudden cracking through changes of temperature, can be reduced to a minimum by careful work. If eyes crack without apparent cause it is usually a sign that they are cheap so-called "stock" eyes, where quantity rather than quality is aimed at. In 1852 the method adopted in France for making eyes was as follows: On the broadly-pressed end of a small colourless, transparent rod of enamel, the pupil was first made, and the iris was then formed on this by means of a small, thin, pointed, coloured enamel rod, the designing of the iris being made possible by melting the point of this rod. In Paris the good eyes are so made. A glass tube, closed at one end and of the colour of the sclerotic, is next blown into the form of an oval, and in the middle of this a hole is melted, the edges of which are rounded off evenly, and pressed a little outward. The iris is then placed in this opening and well melted in. A thick coating of glass remains behind. The eye is rounded off, the protecting rim of the white coat is smoothed with a metal rod, and this coat is thereby joined to the sclerotic. By means of a thin, pointed, red rod the blood vessels to be seen on the hard coat of the human eye are then melted in. The superfluous back part of the eyeball is melted off, thereby giving to the eye the desired form. The eye is finally placed on

hot sand, where it gradually cools off. Glass eyes are made in quite a different manner in Lauscha, the centre of the industry in Germany, where their manufacture is altogether a house industry. The eyes are usually made by one member of a family, and the art is handed down from one generation to another. A gas flame is used for melting the glass, and the method of manufacture is as follows: A small drop of white glass is put on the white blown ball from which the sclerotic is to be made, and is then blown so as to make a circle about eight millimetres (0·315 inch) in diameter. On this circle the structure of the iris is built by means of thin variously-coloured glass rods. A drop of black glass makes the pupil. Over the finished iris crystal glass is melted in order to imitate the cornea. The further manufacture is similar to that given in the first description.

THE MARSEILLES PEANUT-OIL INDUSTRY.

Peanut oil ranks next to olive oil in popular favour, being generally preferred in France to cotton oil. It is highly rated as a salad and a cooking oil, and is used extensively in the manufacture of margarine and by sardine packers. It is frequently mixed with olive and other vegetable oils. The industrial grades obtained from the Indian nuts, and the second pressings of the African varieties, are consumed mainly by the soap-making industry, but a certain proportion is also employed for illuminating and lubricating purposes. The Marseilles mills produced in 1910, 170,000 tons of peanut-oil cake. The cake is used for cattle feeding. About 80,000 tons are exported annually, chiefly to Germany and Scandinavia. Peanuts in the shell are never ground whole in the Marseilles mills. On the contrary, expression of the oil is almost invariably preceded by a careful preparation of the nuts, particularly in the case of edible oil. The peanuts are crushed only after having been cleaned and decorticated, and after every effort has been made to remove entirely the germs and the red skin covering the kernels. All these operations are done by machinery. According to the United States Consul-General at Marseilles, the peanuts undergo a preliminary cleaning in a rotary sieve; they are afterwards brought by a lift to the decorticating machine and passed through grooved rollers so adjusted as to husk the nuts without crushing the kernels. The separation of the husks and kernels is effected by ventilation. The germs, sprouts, and red skin still adhering to the kernels after the husking process, are stripped off by friction against the coarse-wired meshes of a rapidly oscillating sieve, the operation being completed by a ventilator connected with the apparatus. It is extremely difficult, however, to detach the red cuticle entirely from the kernels, and in the case of new crop nuts it is said to be a practical impossibility. After the kernels have been cleaned, they are ground by a crusher provided with two pairs of rollers. The mass emerging from the rollers falls into a "sasseur," or sifter, which separates the coarse from the fine meal, the remaining stones and other foreign substances having been eliminated by an aspirator. The meal is then put into hair bags and subjected to hydraulic pressure, from twelve to fifteen bags separated by metal plates being pressed at the same time. A bag contains about ten kilogrammes (twenty-two pounds) of meal. The first pressing, which furnishes the high-grade oil, is made without heating the meal. This pressing lasts usually about one hour. For the second pressing the bags are generally emptied, the meal reground, and brought to a temperature of 86° to 122° Fahrenheit, according to the quality and condition of the nuts. The same amount of pressure is applied as for the first pressing, and the same press may be used. A smaller yield but a finer grade of oil results from the second pressing when the supplementary grinding of the meal is dispensed with. In some mills a third pressure is applied, but this is an unusual practice. The yield of oil varies with the origin and condition of the nuts. The Senegal peanuts in the shell yield about 33 per cent. of their gross weight, the Gambia peanuts 31½ to 32 per cent. Both of these varieties yield from 21 to 23 per cent. on the first pressing, and 10 to 11 per cent. on the second pressing. The average oil yield of the shelled peanuts is about 39 per cent. for the Indian nuts, and 42 per cent. for the Mozambique. After running from the presses peanut oil does not need refining, but is simply filtered. It is then fit for consumption as salad oil. Bleaching is resorted to only in order to produce the white oil required in the manufacture of margarine.

THE RUSSIAN CAVIAR INDUSTRY.

The ever-increasing demand, and the diminishing supply, of sturgeon caviar led the fishermen of Eastern Siberia to experiment with salmon roe, which had not only been considered useless for human consumption but had even been looked upon as injurious to health. Up to 1907 the fishermen in the neighbourhood of Nicolaevsk considered salmon roe as valueless, but from that time it was demonstrated that caviar could be made so as to prove commercially profitable, and of such a quality that, although it cannot compare with the taste of the sturgeon caviar, it is nevertheless a great delicacy. In the preparation of salmon caviar for the market the following are the methods adopted. Along the sea-coast double-sided traps are used to catch the salmon, whereas in the rivers, in addition to drag seines, traps are used opened at the lower end only, so as to catch the fish moving upstream. No special care is taken with the fish from which it is intended to remove the roe, except that they must be absolutely fresh, and the sooner the roe is removed after capture the better the results will be. Should it be impossible to remove the roe from the fish

immediately after they are caught, they may be kept up to twenty-four hours in cold water, provided they are not confined in a small space. By this is meant that a barge-load of fish covered with cold water would be useless for caviar if kept for that length of time. The eggs are removed in the ordinary operation of cleaning the fish, the only special care necessary being to avoid rupturing the gall bladder, as this would ruin the caviar. After the roe is removed, the eggs are passed through a galvanised iron-wire sieve, copper sieves having been found injurious. During the short time that experiments have been made in the Amur River and Kamchatka it was found that the best caviar is obtained from fish over four years of age, and the best quality is obtained from the king salmon in Kamchatka. According to the American Consul at Vladivostok, there are differences in the caviar produced from the various species of salmon, that is, spring, summer, and autumn, and a marked difference has been noted in eggs taken from fish caught at or near the sea-coast, as compared with fish caught farther up the river, and it has been found that the eggs taken from fish caught far upstream are too ripe for caviar manufacture, as the completed product turns yellow, whereas good salmon caviar should be a bright golden red. After the eggs have been passed through a sieve they are washed in clear cold water and then immediately soaked in brine, and are not in any way drysalted. In addition to pure water and salt, a small quantity of greyish-white powder is mixed with the solution, and this constitutes the secret part of the process. It is believed that this powder is salicylic acid, and possibly a little borax, but experiments could be made which would show if these answer the purpose. The entire success depends upon the strength of this solution, and where methods are the crudest the peasants who prepare caviar test the strength by taste, but a brine gauge may be used for this purpose, and the salt solution should be from 19 to 22 per cent. Should the solution be too strong there is no method of removing the salt from the caviar, and the latter is ruined. The addition of the powder is to counteract the bitter taste in the salt, presumably caused by iodine, as well as for preserving the caviar. The eggs should remain in the solution from twenty-five to forty-five minutes, according to the strength of the brine and the temperature. They are then placed in bags and subjected to heavy pressure. The method employed in Eastern Siberia is to place the bags between two blocks, the upper of which is pressed towards the lower by a pole lever, at one end of which a man suspends the weight. This pressure, although great, does not crush the eggs, as they are flexible, and it causes a shrinkage in the weight of the caviar of about 40 per cent. After being subjected to this pressure the caviar is immediately packed into wooden kegs and the process is completed, no oil or other substance being added. Selected caviar is packed in one-pood (36 lbs.) kegs, the ordinary caviar in kegs weighing from three to nine poods each. Care is always taken in the kind of wood used, as it has been proved that lime and oak spoil the caviar, the latter causing it to turn black. The principal market for salmon caviar is European Russia, more particularly Moscow and St. Petersburg, and it is introduced into other countries of Europe. This caviar is known on the Russian market as "Kitovia" or "Krasnia Ekra" (salmon or red caviar).

PEAT UTILIZATION IN GERMANY.

Efforts are being made in Germany to improve the cultivation of marshes and moorland. The success attained in this direction in the Netherlands has attracted attention in Germany, particularly since Dutch gardeners and truck farmers have predicted that, were the marshes of Prussia cultivated like those of Holland, the German canned fruit and vegetable industry would conquer the markets of the world. The German marsh and moorlands cover an area of about five million acres. The largest districts by far are in Prussia, especially in the provinces of Hanover and Schleswig-Holstein, and also in Pomerania, Brandenburg, Posen, and Ost-Preussen. The best quality of peat from German soil, so called air-dry peat, contains about 45 per cent. of carbon according to the American Consul at Stettin, 1·5 per cent. of hydrogen, 28·5 per cent. of chemically-bound water, 25 per cent. of hygroscopic water, and small amounts of nitrogen. The annual production of peat in the Empire amounts to about 11 million tons. Regarding the heating qualities of the best peat, it has been established that the average peat is equal to dry beechwood at similar weight and equal to coal of half the weight. There is a vast difference, however, in heating power between the different grades of peat at equal weights. If the ash exceeds 25 per cent. the peat is deemed not adapted for fuel purposes. The percentage of ash can vary from one-half of 1 per cent. to 50 per cent. The industrial utilization of peat for lighting purposes has been attempted for many years in Germany, but as yet there has been no satisfactory solution of the problem of how to produce power-gas from peat more cheaply than from coal. In conjunction therewith the generation of ammonia and of electricity has been attracting much attention in scientific quarters, and at the last annual convention of German scientists and physicians this problem was discussed as a result of new views and investigations presented by Dr. Caro, of Berlin. In collaboration with Professor Frank, of Charlottenburg, Dr. Caro discovered a method for the economic utilization of peat which he claims avoids former mistakes, and which he described as follows. The generator consists of shaft-like ovens, where the burning of the peat is conducted in a way admitting limited quantities of air. Thus also, a dry peat in pieces can be treated, and produces a gas strongly impregnated with tar fumes, which gas, after purification from tar, will furnish a useful heating and

power gas. The inventor found that if the gasification process is properly conducted, peat containing as much as 60 per cent. of water could be used. Peat having a percentage of water above 60 could be dried down to this figure by storage in the open air. This process, Dr. Caro asserts, permits the manufacture of a good heating gas during the entire year, and he claims that it can be used in connection with the generation of electricity. In view of the absence of constant water-power in Germany, he thinks that the invention will cheapen the cost of generating current. Another result of the discovery is the extraction of nitrogen by this process, 85 per cent. of this element contained in the peat being recovered therefrom. This nitrogen can be converted into ammonia by the introduction of steam. The method admits of the production of ammonium sulphate, and thus furnishes agriculture with a valuable fertiliser. The Prussian Minister of Agriculture is now engaged in preparing a comprehensive law giving the Government extensive power to stimulate by direct financial assistance, as well as by the use of all available governmental facilities in the broadest application, all efforts for the cultivation of the German marshes and moors, although 90 per cent. of the Prussian high moorlands are in private hands.

JAPANESE RAILWAY STATISTICS.

In the course of his paper on Japan, read before the Royal Statistical Society, Mr. Charles V. Sale gave some interesting figures relating to the Japanese railways. With considerable foresight, the Government acquired the private undertakings before the capital value of these had (as in our own case) increased in such a manner as to render this impracticable. The purchase price was 48·8 millions, more than double the cost, showing how land and labour had increased in value since the railways were commenced. This purchase was authorised in 1906, some twenty-five years after railway construction had been commenced on an appreciable scale. In 1872 only eighteen miles were open, owned by the State. This had increased to 300 State and 293 private-owned by 1888, to 1,532 State and 3,251 private by 1906, and to 4,542 State and 478 private by 1909. Figures for the rolling-stock are also given. In 1872 Japan possessed 10 locomotives, 58 passenger coaches, and 75 freight wagons. At the time of the conversion to State ownership, there were 1,717 locomotives, 5,340 passenger carriages, and 27,183 goods wagons. At present there are 2,156 locomotives, 5,956 passenger carriages, and 34,045 goods wagons. A noticeable feature is the large proportion of locomotives to trailed vehicles, the proportion being 1 to 18·9 in 1906, and 18·5 at the present time. The proportion for English railways is one locomotive to 36 railway-owned vehicles. The use of a heavier locomotive is probably rendered impracticable by the narrow gauge (3 ft. 6 in.) and by the steep gradients.

The proportion of earnings to expenses was, in 1909, 100 to 53½, very good, although considerably increased of late years. In the same year the average proportion in the United Kingdom was 62 per cent.

The receipts from passengers were under a million pounds in 1891, increased to 4·29 millions by 1908, and 4·55 millions in 1909. The number of passengers has increased from 22·8 millions in 1891 to 146·9 millions in 1909. The receipts per passenger have increased, although the mileage per passenger has decreased slightly, arguing probably, shorter individual journeys.

The goods traffic brought in £284,000 in 1891, 2·8 millions in 1908, and 3·7 millions in 1909. The receipts per ton carried have considerably increased, standing at 35 pence, while the mileage per ton has also increased.

It will be noted that the total net earnings on the Japanese railways are £3,960,000 on a capital of £80,038,000, or a proportion of 4·9 per cent., whereas the English net earnings were £45,136,000 on a capital of £1,314,400,000, a percentage of only 3·4. The total receipts from all sources (a rather difficult figure to arrive at accurately) are given as 8·5 millions for Japan, and 120·17 millions for the United Kingdom. This works out at 10·6 per cent. for Japan, and 8·1 for the home railways, a lower rate which may be partly due to capital expenditure not yet remunerative, as well as, in net figures, to the expense of the directorates.

The only analysed table given is that for 1907, from which we learn that the maintenance expenses per mile were £190, as against £487 in the United Kingdom, and general expenses only £49, as against our robust figure of £270. Certainly the rates, taxes, and Government duty, from which, of course, a State railway is exempt, add a noticeable item to the expenditure of our railways, amounting to £228 per mile. The omission of this item would better the percentage of receipts to capital about ·3 of a pound, still leaving it considerably under the 4·9 per cent. of Japan.

Taking the total mileage of 1909 at 4,542, we have a capital expenditure of £17,600 a mile. The United Kingdom figures at £56,000 per mile by the same calculation, but against this has to be reckoned both wider gauge, far more expensive land, and extensive investments in docks, shipping, etc., which do not enter into the mileage.

THE BROOM INDUSTRY OF HONDURAS.

In the districts of Santa Barbara and Ilama in Honduras, there has for many years been carried on, in a small way, and as a by-product of the manufacture of panama hats, a broom industry which is now beginning to attract attention. The panama hats are made from the fibre of the Carludovica palmata, the young shoots of which are cut

just as they begin to flower. The fibre grows in concentric folds around a central stalk. It is peeled off for the hat-makers according to the fineness desired, dried in the sun, and bleached with sulphur. The United States Consul at Puerto Cortes says that the natives call these young shoots "candles," because of their shape. They are from two to three feet long, and when the outside fibre is stripped off there is left a central stalk or core, which is split, flattened out, and cut into strips for making brooms. The strips are cut into lengths of ten to fifteen inches, which are firmly tied in the centre around a broom-handle, doubled back, tied again and trimmed to the desired length and shape, and placed on the market by sending out mule-loads to the various cities and towns and hawked, *en route*, at the wayside houses and plantations. They are readily purchased by the merchants of the country in exchange for goods at prices equal to about sixpence or sevenpence, and by them retailed to the general public. They are extensively used in the railway service, the management of which finds them perfectly satisfactory, and much cheaper than the imported article. The fibre has a good spring in it, and is said to be very durable. It is proposed to ship the fibre in bulk to broom-makers in the United States in order that they may put it to certain domestic and business uses.

HOME INDUSTRIES.

The Coal Industry.—There is some reason to fear something like a national strike among the coal miners before the year is out. Dissatisfaction is rampant in Northumberland and Durham, as in Wales. And the Eight Hours Act has much to do with it. The objections to this ill-advised measure have frequently been stated in these Notes. They are restated with much force by a correspondent of the *Times* (August 31st) as follows:—"The miners were led to believe that this Act would be a boon to them. It is proving otherwise. Some of them feel that they have been betrayed, or at least deceived, by their leaders. Hence the spread of indiscipline. Others imagine that the employers are 'putting the screw on' out of spite against the men and their Federation for securing the Eight Hours law. Hence the unusually strong disposition to strike. It is not an abuse of language to say that this new law is a curse on the mining industry. Here we see an attempt to impose a uniform law upon an industry in which the conditions vary widely between district and district, and even between mine and mine, and as a result we have friction and discontent throughout the country. Even the problem of mining accidents has been intensified by this measure. Before we got the Eight Hours Act our fatal accidents represented four lives per working day. Since the Act was passed we have been killing our miners at the rate of six per day. Non-fatal accidents have, of course, increased concurrently, and this is the outcome, mainly, of the 'speeding up' consequent upon the limitation of hours. Besides this increase of danger, our miners have got reduced earnings, inconvenient shifts, and the loss of much week-end leisure. For example, it was the custom at many pits, before the Eight Hours Act was passed, for the men to work long shifts on mid-week days in order to have ample time for gardening and sport at the week-ends. The men frequently had clear spells of leisure from Friday night till Tuesday morning. Now, with the law limiting the working hours to eight each day, it becomes necessary for the men to be in the pits one and two shifts more per week—that is, they have to work Saturdays and Mondays in order to 'make wages.' Thus, including the time occupied getting to and from work, the average miner has less time for home life than he had before the State attempted to give him more time to himself. The Act has defeated its own chief object. At many of the pits in Northumberland, where the men have voted for a strike, and in Durham, where there is a similar movement to get back to the conditions which existed before the Eight Hours Act was passed, this measure has done immense injury to the workers. It has necessitated the introduction of what is called the 'multiple shift' system. This means that where formerly the men worked two short shifts daily—the 'fore' shift and the 'back' shift—and the boys on a regular single-shift system, the men are now on three or four shifts, extending to nearly the full twenty-four hours daily, and the boys are on a double-shift system. The result is that in households where there are three or four sons, or lodgers, as well as the father employed at the pits, and on different shifts, the workers are going out and coming in at almost all hours of the day and night; the women have scarcely ever done preparing meals and changes of clothing; the houses are always upset; evening leisure is cut down; the boys cannot attend classes; and the men have to hold their lodge meetings on Sundays. Domestic and social customs are completely disorganised, and the public health authorities already note an increase in the infantile death-rate because the women have less time to attend to their children. It may with truth be said that alike on earnings, leisure, health, and safety the Eight Hours Act has, almost everywhere, had results the very opposite of what the men were led to expect."

The Settlement of Labour Disputes. — It is pleasant to be able to note that Sir Charles Macara has received the signatures of more than twelve hundred prominent men, in commerce and industry, in support of his suggestions for the settlement of labour disputes. It is believed by the supporters of the scheme that the creation of a new department, with a competent, non-political, permanent chairman, deputy-chairman, and staff, assisted by an advisory board composed of the most prominent men, representing both capital and labour, connected with the great staple

industries, and possessed of practical experience in the settlement of disputes, would tend to the promotion of friendly settlements when the disputants have come to a deadlock. Anyway, the experiment seems to be worth trying. The scheme concerns itself with deadlocks only, and would not in any way interfere with existing organisations for dealing with labour disputes.

"*Kilometre Books.*" — The General European Agent of the national railways of Mexico, referring to a communication he made to the press in May last—in which he said that the national railways of Mexico were prepared to issue "kilometre books" to genuine commercial travellers, provided their applications were endorsed by a Mexican chamber of commerce, a privilege not at that time extended to the representatives of foreign firms, since the local chambers declined to support their requests—says that he is now in a position to advise that this disability has been removed, and the kilometre books can henceforth be issued to any identified commercial traveller. Applications should be addressed to the agent, and bear the signature of the secretary or other authorised official of any chamber of commerce of which the firm may be a member. Manufacturers will recognise the advantage of being able to secure these books, as, apart from some saving in cost over the ordinary fares, and privileges as regards conveyance of samples, a considerable amount of inconvenience and delay is avoided.

Substitutes for Cotton.—The high prices and scarcity of cotton have encouraged German manufacturers to turn their attention to the cultivation of substitutes, among them being kapok. The German Committee on Colonial Agriculture has sent representatives to the Fibre Congress, to be held in Surabaya, Java, to study the cultivation of sisal, manila, hemp, jute, and kapok. It is stated that much is expected from the cultivation of kapok and calotropis, not only in the German colonies, but also in Mexico, Brazil, and other South American States. The kapok crop for the current year is estimated at 70,000 bales. Herr Stark, of Chemnitz, has made experiments with a view to determine the possibilities of kapok, and it is said that he has succeeded in bleaching it. It is also being mixed with wool and silk waste and spun into yarn by the carded woollen process. But it will be a long time before kapok, or any other substitute, plays an important part as raw material for the manufacture of goods for which cotton has hitherto been used.

Vacuum Cleaning and Mills.—A good deal of attention has been given in recent years to the application of vacuum-cleaning to textile machinery. Ordinary hand-cleaning of this sort of machinery is necessarily laborious, and therefore expensive, owing to its complexity, but vacuum systems that have proved successful for domestic purposes are not equally so with textile machinery, owing to the nature of the dirt to be got rid of, which is mostly oily fluff. But an invention described in the *Textile World Record* is said to overcome most of the difficulties. It is a combination of the blowing and the suction systems. A powerful air-blast is used to detach the dirt, which is then collected by a low-pressure vacuum and deposited in a canvas bag. The apparatus is small, light enough to be carried by the operator down the narrow alleys between frames, is easily worked, since all that is required to change from air-blast to suction is the closing of a valve, and the motive power is economical, being obtained from the compressed air supply which works the humidifier installation. One advantage of working by compressed air is that cleaning can be done when the mill is standing. But there is said to be danger of blowing dirt on to yarn and cloth in operation.

Flax-mills and Wages.—For the first time in the history of the industry a Flax Workers' Union has been formed, and it would seem that flax workers are in need of some such body to champion them. At the present time several hundreds of women are on strike for an advance of 2*s.* a week on their wages, and the men are demanding a minimum wage of £1 a week. "Even when in full work," the officials of the council say, "it is as much as these operatives can do to keep body and soul together. The best standing wage in a week, including bonus, is 11*s.* And, as many of the women are widows with families to keep, and others have sick or out-of-work husbands or other relatives to help, there is no chance of saving; so that the instant wages cease they have nothing to draw upon." The best rate of pay appears to be a standing wage of 9*s.* 6*d.* a week, with a bonus of 1*s.* 6*d.* (forfeited if a day's work is lost). Some girls after three or four years' employment are able to earn only 5*s.* 9*d.* (bonus included), and a woman who has worked at the mill all the best years of her life draws a wage of 8*s.* 6*d.* There would seem to be ground here for a struggle for a better wage.

CORRESPONDENCE.

CANTOR LECTURES ON "ETCHING."

As Mr. Wedmore is quite unable to explain away the ignorance, prejudice, or carelessness which distinguished his Cantor Lectures, he has descended to personal abuse of me, couched in the most misleading terms, intended to injure me, if possible. His article, which he refers to, concerning my work, was not for my publishers' exhibition, as he incorrectly states—they were not giving one—but for the Grolier Club of New York; and Mr. Wedmore omits to say that his article was rejected as soon as read—it was not considered worth printing.

JOSEPH PENNELL.

3, Adelphi Terrace House, Robert Street,
Strand, London, W.C.,
September 1st, 1911.

NOTES ON BOOKS.

LES FAUVES D'AFRIQUE PHOTOGRAPHIÉS CHEZ EUX. Par Radcliffe Dugmore. Paris: Hachette. 1910.

The author of this book is presumably a Frenchman, as he writes in that language, though he has not a French name. According to his own account his previous hunting experiences have been in North America, where he abandoned the rifle for the camera. "Pendant de nombreuses années, je fus un chasseur plus enthousiaste que quiconque. Aujourd'hui, après en avoir passé dix avec la chambre noire au lieu du rifle, je n'ai pas le moindre désir de tirer des coups de feu. J'estime que ce n'est plus pour moi suffisamment émotionnant, et que cela constitue un sport trop aisé pour être intéressant." Certainly there can be no lack of excitement in a sport which requires the sportsman to spend the night in a frail shelter hut constructed on the ground, with three lions prowling and growling about ten yards off, in the hope that they will pose themselves in front of a camera, with a flashlight ready to be touched off if they do. It is much more difficult to photograph an animal than to shoot him, or at least it is more difficult to get within photographic range than gunshot range. Probably, once you are near enough, it may be easier to miss him with the gun than with the camera.

Mr. Dugmore has, of course, his predecessors. Mr. Roosevelt's party comprised an official photographer in the person of his son, who got some marvellous pictures. A German sportsman got some remarkable flashlight pictures of lions and leopards a few years ago, and a picture of a Rocky Mountain goat a few feet away adorns a volume of another American sportsman who carries a camera. But our author need not fear comparison with any of his competitors, whether with flashlight or daylight. There is certainly no better flashlight photograph of a lion (or rather lioness) than the one facing page 206. Another (facing page 86) is interesting and valuable scientifically, but pictorially not quite so perfect. Another wonderful picture is the charging rhinoceros, taken full front a few yards off, before he was turned by a bullet from the photographer's companion. There are many others worthy of mention—giraffes, buffaloes, zebras, antelopes, etc.—all taken by stalking at close quarters, and a large collection of telephotographs. They are admirably reproduced by some phototype process, being apparently slightly enlarged in some cases, though in others they look as if the prints were the same size as the original.

The author does not give us much information about his apparatus or methods. He uses both plates and films, but prefers the former. He develops at once, and takes a print on self-toning paper, in case of accident to the plate. He uses ortho-chromatic plates without a screen. He employs an electric arrangement for the simultaneous firing of the magnesium and the working of the shutter. For the photograph of the lioness above mentioned, three cameras were set up, eight or ten feet apart, and nine metres (say thirty feet) from the carcass which served as bait.

GENERAL NOTES.

PREVENTION OF MALARIA IN RICE-GROWING DISTRICTS.—As a remedy for malaria in the rice-growing districts bordering on the Po, the rearing of fish is said to have given good results. This region, which covers an area of about 200,000 hectares (nearly half a million acres), is more or less unhealthy. The young carp are turned out into the flooded fields towards the end of June, and greedily devour the larvæ of the insect life which appear to be a cause of the disease. The cost of the young fish does not exceed 4 to 5 francs per hectare (1*s.* 4*d.* to 1*s.* 9*d.* per acre). It is stated also that the crops are improved by the rearing of the carp to the extent of 4 to 5 quintals of rice per hectare (2 to 2½ cwts. per acre).

CANADIAN OYSTER-BEDS.—According to a recent official report for 1910, the oyster-beds of the Maritime Provinces are very seriously depleted, and many are entirely non-productive. The natural live oyster-beds of New Brunswick, Prince Edward Island and Nova Scotia are yet, however, of considerable value, while much ground is available for profitable private culture. It has been recommended that the Dominion Government appropriate sufficient money to establish new, and restock exhausted, beds, either by natural or artificial means, and that liberal inducements be offered through a system of leases to persons who will undertake, under stringent regulations, to engage in the oyster business. It is claimed that many of the oyster-beds of Prince Edward Island have been destroyed by farmers, who have sought what is called mussel mud to place on their land to supply the lack of lime in the soil. This is now regulated by law, and no mussel mud can be taken within 200 feet of a live oyster-bed. The mud is collected by means of a horse-drawn scoop worked through holes in the ice. Thousands of loads have thus been taken and placed upon the land.

SHIPBUILDING ACTIVITY IN ITALY.—According to a recent report to the shareholders of Ansaldo, Armstrong and Company, of Genoa, the shipbuilding industry appears to be in a flourishing condition in Italy at the present time. Amongst the principal works which this firm have on hand for the Italian navy are the ironclad "Giulio Cesare," now on the stocks at their Sestri Ponente yard, for which they will supply the turbines as well as the guns. This firm are also constructing the turbine machinery for four other vessels, viz., the cruisers "Dante Alighieri," "Leonardo da Vinci," "Conte

di Cavour," and "Quarto," which are being built by other firms. Last year they built six torpedo-catchers, and supplied the turbines for the cruiser "San Marco." Besides this work for the navy, the turbine passenger steamer, the "Città di Catania," was built and launched by the same firm, who also supplied the turbines for another passenger vessel, the "Città di Palermo," built elsewhere. Amongst other vessels now in construction may be mentioned a torpedo-catcher for the Chilian Government, and a cruiser for the Ottoman navy, not to speak of tugs and other smaller craft. At the Sampierdarena works the same firm completed sixty-three locomotives last year, and have on hand orders for fifty-eight more at the present time.

Locomotive Construction in Italy.—The administration of the Italian State Railways has lately placed contracts for constructing 193 locomotive engines at prices ranging from 1·64 to 1·75 lire per kilogramme for the engines, and at 90 centimes for tenders. Taking the English ton at 1,016 kilogrammes, these prices would correspond to from £66 13*s.* to £71 2*s.* 5*d.* per ton for the engines, and £36 11*s.* 6*d.* per ton for the tenders. Eighty-one locomotives are to be built at Milan, 60 at Sampierdarena, near Genoa, 32 at Naples, and 20 at Saronno (Lombardy), and are to be delivered in the course of the present year.

Proposed Railway under Lagoon at Venice.—It is now proposed to connect Venice with the island of Lido by a tunnel under the lagoon. This island, a favourite summer resort of the Venetians on account of its unrivalled beach and excellent sea-bathing, is situated on the Adriatic about two miles from the city. The terminus of the line would be in a central position, close to the Piazza di San Marco, and the Riva degli Schiavoni, at about 8 metres (26¼ ft.) below the sea level. The tunnel, 3,600 metres (2¼ miles) in length, would pass in a straight line, under the islands of La Giudecca and San Georgio, to the terminus of Lido, at a spot called the Quattro Fontane. The line and lifts would be worked by electricity, and frequent trains could perform the journey in five minutes.

Cure for Mildew of the Vine.—Many remedies have been tried against the ravages of the various insects and fungus pests, which of late years have devastated the vineyards of France and Italy. The opinion of winegrowers in both these countries is much divided as to the value of the various preparations advocated for the purpose. The poisonous nature of the arsenical salts which enter into the composition of many of these is a serious objection to their adoption. Nicotine, on the other hand, though efficient, in many cases, is not altogether harmless to the person using it, and is liable to cause intoxication in some cases. In many parts of France, "Lysol" has proved a most valuable panacea, when used with a solution of sulphate of copper and lime-water, for spraying the leaves and grapes. The proportion of "lysol" used for the first treatment of the vines is half a litre per 100 litres (about 1 pint to 22 gallons) of solution, which should be well mixed. For subsequent treatments the proportion of "lysol" should be doubled. Care must be taken to spray every part of the leaves and grapes with the solution.

Peridot Stones of Ancient Egypt.—A deposit of "peridots" has recently been discovered in Alexandria. These stones, which are amber in colour, for many years have been found in large quantities in Upper Egypt. The finder has secured a concession to work the ground, and has uncovered several thousands of these stones at a depth not greater than ten feet. It is believed that the peridots were buried in the foundations of houses of the ancient Egyptians, and in tombs, as an omen of luck. The stones now found are estimated to have been buried for over 1,500 years. Their value is not great, the price of the stone of the average weight of three carats being a little over four shillings. The discoverers of the Alexandria deposits have also secured a concession to work ground on the islands of Rahamah and Kad-Ali near Assab, in Red Sea territory belonging to Italy. Some peridots have recently been found there, and it is believed that the deposit is a large one never before mined.

Importation of Autocars to England.—Judging from a French journal, England appears to be, by far, the largest importer of autocars of any other nations. In 1910 she imported to the value of 141,945,000 francs (£5,677,800), or more than ten times that imported by the United States, which amounted to 13,686,000 francs (£547,440), whilst the value of the cars imported to Germany reached 12,285,000 francs (£491,400); to France, 9,320,000 francs (£378,800), and to Italy, 5,120,000 francs (£204,800).

Population of Messina.—It may come as a surprise to many to learn that, according to the general census made throughout Italy last spring, the population of Messina is now 123,689. The number of inhabitants of that city before the disastrous earthquake at the end of 1908 was upwards of 172,000.

German Revenue-Producing Administrations.—Some interesting information is given by Count de Salis, Councillor of His Majesty's Embassy at Berlin, in his report just published (No. 4626 Annual Series) on the finances of the German Empire touching property owned by the State in Prussia. The domains include a large quantity of agricultural land, part of which is let, while the rest is managed by State officials. They also include mineral-water springs and baths, which bring in more than £100,000 a year. The sale of timber from the State forests brings in nearly £6,000,000. Coal brings in more than £9,000,000, and the combined sale of iron, silver, and lead over

£1,000,000. The State also owns extensive potash works, and is accordingly a member of the Syndicate which has the exclusive right of carrying on the potash trade in Prussia. The State owns 32,000 kilometres of railway out of a total of 34,000 kilometres. The small amount owned by private companies comprises almost entirely what are known as secondary railways. The total capital outlay on railways in Germany up to 1907 is officially estimated at 781,000,000 marks. The Prussian railways represent an investment of over 400,000,000 marks. The State derives a net revenue of nearly £500,000 from the State lottery. Under present arrangements there are two lotteries in the year, the profits of the State being derived from a deduction of 15½ per cent. from the sums distributed as winnings. The celebrated China manufactory at Charlottenburg, founded by Frederick the Great, would appear to be carried on rather for the encouragement of art than for purposes of earning revenue.

Protection of Crops from Hail.—The damage to the crops in France from hail is estimated at 150 millions of francs (six millions sterling) every year. Many remedies have been tried, with more or less degree of success, in order to mitigate the evil, not only in that country, but also in Italy and Austria. The principal means adopted for the purpose during the last ten years has been the discharge of explosives during storms in the immediate vicinity of the crops threatened. In many parts of France, and more particularly in the wine-growing departments, associations of the landowners and cultivators have been formed for the mutual protection of their vineyards. In the Beaujolais district last year, no fewer than twenty-three of these societies were in existence; they are provided with 387 cannons or mortars. In another part of the same district, but separated by a considerable extent of unprotected country, there are six other societies with 137 stations for the discharge of rockets. These two groups form the "Union des Associations Grêlifuges du Beaujolais," and carry out their operations during storms on a preconcerted plan. In this district there are also several independent associations for *tirs contre la grêle.* The results obtained by these means of defence have, on the whole, been satisfactory in France, where public opinion is more unanimous as to its efficacy than is the case in Italy. The immediate effects of the discharge of explosives, either from cannon, mortar, or by means of a firework (*fusée*), is said to be to abate the thunder and lightning, to stop the wind, and to melt the hailstones before they can reach the ground or injure the plants.

Motor-car Trade in Egypt.—The total value of the motor-cars imported in 1910 by Egypt amounted to 968,150 francs (£38,726). Of this amount, about two-thirds were paid for cars of French make, whilst England figures for 191,700 francs (£76,680), or about one-fifth of the total value.

Chinese Industrial Development.—In his report on the trade of China just issued, Mr. H. H. Fox, Acting Commercial Attaché to his Majesty's Legation at Peking, refers to that industrial awakening of the Chinese people which has been so noticeable during the past decade, and which must, sooner or later, alter the character of their commercial relations with foreign countries. Mr. Fox does not think that this movement need cause us serious anxiety, for the present at any rate. In his opinion Chinese factories will be unable for some time to come to turn out any but low-grade articles, which will only compete with Japanese productions of a similar class. The finer qualities of goods for which the spread of Western civilization is bringing an increasing demand, will continue to come from abroad. Moreover, the general use of foreign goods in China is still confined to the towns and districts situated on the coast or along the great rivers, although before long railways will open up vast areas where at present foreign goods are practically unknown. A factor which militates against the success of Chinese industrial undertakings is their dislike of employing foreign managers and engineers. "Just as in their schools and colleges, the Chinese are endeavouring to assimilate Western languages and sciences by means of native professors who themselves possess no more than a smattering of the subjects they teach, so in factories, when they have laid down at great expense an up-to-date plant of complicated and delicate machinery, they dispense with the foreign expert almost as soon as the machines have started working, leaving them to the tender mercies of native engineers, who are helpless so soon as anything goes wrong." And as on the technical, so on the commercial side of the undertaking. The Chinese are not yet capable of conducting large commercial enterprises, such as steamship companies, iron works, etc., on good business lines, and their promoters deliberately refuse to avail themselves of foreign business knowledge and experience.

The Queensland Timber Industry.—The forest resources of Queensland are extensive, amounting to 40,000,000 acres, or 9·32 per cent. of the whole area of the State, while 3,836,191 acres, or 0·89 per cent. are specially reserved by the Government for timber. The forests of Queensland yield a great variety of woods noted for strength, durability, and beauty. The eucalyptus dominates the forests, which also contain iron bark, grey, spotted, and red gum, black butt and turpentine. The conifers, too, are numerous, including Moreton bay and brown, and bunya-bunya pines. Among the brush timbers of fine grain are red cedar, beach, tulip wood, and rosewood. In the extensive plateaus west of the dividing range off from the coast there is but little timber, and in the vast basin of the interior usually only stunted eucalyptus are found. The quantity of timber cut and sawn in Queensland in the latest year for which the particulars are available was 100,760,000 superficial feet, valued at £660,000.

Sir Raymond West, K.C.I.E., M.A., LL.D.
Field-Marshal Sir George Stewart White, V.C., G.C.B., O.M., G.C.S.I., G.C.M.G., G.C.I.E., G.C.V.O.
Sir James Wilson, K.C.S.I.
Colonel Charles Edward Yate, C.S.I., C.M.G., M.P.
S. Digby, C.I.E. (Secretary).

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

BREWING AND MODERN SCIENCE.

By Professor Adrian J. Brown, F.R.S.

Lecture IV.—Delivered February 27th, 1911.

THE FERMENTATION PROCESS.

Although no course of Cantor Lectures on brewing has been given since Dr. Graham lectured on the subject in 1873, fermentation, a subject most intimately associated with brewing, has been discussed on several occasions. In 1884 Professor Hartley gave a series of lectures on "Fermentation and Distillation." In 1888 Mr. A. Gordon Salamon gave a course of lectures on "Yeast: its Morphology and Culture," in which he reviewed in a very able manner those investigations of the late Dr. E. C. Hansen, of Copenhagen, in connection with yeast, which have exerted such an important influence on the brewing industry throughout the world. Again, in 1892, a course of lectures on the "Chemistry and Bacteriology of the Fermentation Industries" was given by Professor Percy Frankland—a more able exponent of these subjects could not be found.

As, therefore, the subject of fermentation has already been discussed from several different points of view since it was referred to in Dr. Graham's lectures on brewing thirty-eight years ago, I feel that general reference to the subject now is unnecessary. In the time at my disposal, I think it will be better for me to confine my remarks to certain questions in connection with fermentation on which much light has been thrown by recent investigations, and which are of special importance at the present time.

Since the time when that most illustrious man, Pasteur, demonstrated to the world at large that fermentation was a phenomenon

directly associated with cell-life, our views regarding the more precise nature of the phenomenon have experienced marked changes. Probably every one in this room is more or less familiar with the reasons which guided Pasteur, during his study of fermentation, to formulate a theory regarding its prime cause, which was accepted almost universally until quite recent times.

During Pasteur's remarkable investigations, a very striking discovery made in connection with yeast was that this micro-organism was able to grow and lead an active life in an environment deprived of air, or free oxygen. Hitherto the belief had been universal that air was necessary for life, that life perhaps might be able to persist in a dormant condition for a time without air, but that the presence of air was essential for the production of vital energy. Pasteur's investigations demonstrated, however, that a previously unrecognised condition of existence—anaerobic life—was possible. Now this most interesting and striking discovery was made with regard to an organism which was conspicuous for its fermentative power, and the association of anaerobic existence and fermentation in the one organism very naturally suggested to Pasteur that perhaps the two phenomena were interdependent.

When studying the growth and actions of yeast in a fermentable liquid such as malt-wort, Pasteur noticed when yeast was introduced into aerated wort that the whole of the oxygen dissolved in the liquid was very rapidly absorbed by the yeast, and at the same time active multiplication of the yeast-cells by budding took place. Subsequently, when the yeast was under anaerobic conditions, active fermentation of the sugar of the wort was evidenced, and multiplication of the yeast-cells became less rapid and finally ceased altogether. From observations such as these Pasteur was led to regard yeast as an organism endowed with two modes of life—in the presence of air he considered that it lived the life of an ordinary fungus and exhibited the usual actions of cell-life; in the absence of air he believed it took on the new properties of a ferment, and was enabled to ferment sugar. In Pasteur's well-known "Études sur la Bière," a series of most beautiful experiments with yeast under aerobic and anaerobic conditions are described which seemed to confirm this view. Moreover, when Pasteur's investigations were extended to fermentation phenomena other than those occasioned by yeast, the view that the phenomenon of fermentation was the result of anaerobic existence appeared to obtain additional confirmation. In the case of certain lactic and butyric acid-producing bacteria it was shown that the fermentation changes induced by these organisms appeared to depend on the conditions of their existence being anaerobic.

From evidence such as that to which I have very briefly referred, Pasteur was led to formulate his well-known and beautiful theory that the phenomenon of fermentation was a direct consequence of "life without air"—that is to say, that the chemical changes we know as fermentation were the result of vital activity in the absence of free oxygen.

Decomposition of fermentable matter was, according to Pasteur's view, occasioned by organisms living under anaerobic conditions and abstracting the oxygen which was presumed to be necessary for their existence from the fermentable matter. In the case of the fermentation of sugar by yeast, it was known that in addition to the main products of fermentation —alcohol and carbon-dioxide—small quantities of glycerine and succinic acid are produced, and it was suggested that these products might result directly from the removal of oxygen from a small quantity of sugar in the following manner

$$8\ C_6H_{12}O_6 + 6\ H_2O = \underset{\text{Succinic acid}}{2\ C_4H_6O_4} + \underset{\text{Glycerine}}{12\ C_3H_8O_3} + 4\ CO_2 + O_2.$$

As a consequence of this reaction, it was supposed that it further occasioned the splitting up of a very much larger amount of sugar into alcohol and carbon-dioxide, so producing the ordinary phenomena associated with alcoholic fermentation.

Pasteur's theory regarding the connection of fermentation with anaerobic life was very generally accepted for many years. In the year 1892, however, during the course of an investigation connected with the reproduction of yeast, I obtained results which led me to question its validity. In the experiments made by Pasteur to determine the relative fermentative power of yeast under anaerobic and aerobic conditions, complications arose through the reproduction and consequent increase in number of the yeast-cells during the course of the experiments. My investigations of the specific character of the reproduction of yeast-cells by budding demonstrated that when yeast is introduced into a fermentable nutritive solution, such as malt-wort, the cells have a tendency to increase to a definite number in a given volume

of the liquid and then to cease reproducing. This property of the cells is independent of the amount of the food-supply in the fermentable liquid so long as it is kept within certain limits, and is also independent of the number of cells originally introduced into the fermentable liquid so long as the number added does not exceed the maximum number to which the cells naturally increase under normal conditions in the fermentable solution employed. If, on the other hand, a larger number of cells than the maximum is introduced into the liquid, then little or no multiplication of the cells is observed. Hence it appeared that experiments on the fermentative power of yeast could be conducted with a constant number of yeast-cells if the number of cells employed exceeded a certain maximum number.

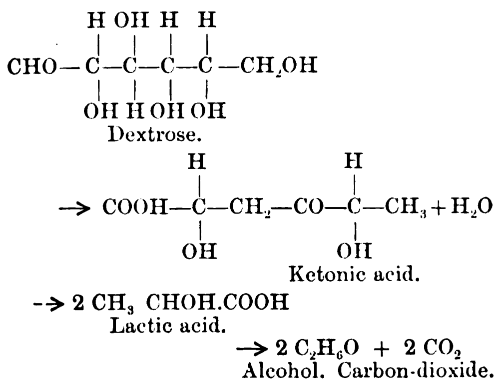
Experiments based on this conclusion were made in which the fermentative powers of equal and constant amounts of yeast under aerobic and anaerobic conditions were measured. I confess, when these experiments were commenced, I was happy in the idea that I had found a very easy means of demonstrating the truth of Pasteur's beautiful theory of fermentation. Great, therefore, was my surprise when I found that the results of my experiments pointed to the conclusion that aerobic existence did not hinder fermentation. After conducting experiments in the most suitable manner I could devise in order to obtain the most complete aeration possible, so far from finding that a supply of free oxygen arrested the fermentative power of yeast, as it should according to Pasteur's theory, it tended somewhat in the direction of stimulating it. Notwithstanding Pasteur's powerful arguments, I was forced to the conclusion that his theory, as ordinarily understood, could not be upheld, and I felt compelled to express this view; but it was much against my will, for the eminent author of the theory was approaching the end of his illustrious career, and was no longer in a position to defend his own views. However, his lieutenant, M. Duclaux, most ably criticised my investigations, and probably the subject would have passed through other developments had it not been for the confirmation my views received from another source, which rendered further investigation on my part unnecessary. I refer to Buchner's discovery that zymase, an enzyme present in the yeast-cell, was the direct cause of its fermentative power.

Hitherto, fermentation of sugar by yeast had been regarded in a somewhat undeterminative manner as an action of the living protoplasm of the cell; this view was a survival from earlier days, when many changes which we now recognise as purely chemical were attributed to the direct action of life, for want of better knowledge. It appears natural to humanity, past and present, when the unknown is encountered to refer it, by way of explanation, to some still more mysterious unknown; we all seem tempted to do it, either through laziness or conceit, possibly through both. However this may be, increasing knowledge, as it gradually throws light on the physiological processes of life, tends to demonstrate that all the phenomena of life may be the outcome of ordinary chemical action. Previous to Buchner's discovery, knowledge of enzymes had been increasing, and many, so-called, fermentation changes had already been traced to their agency; but alcoholic fermentation of sugar, lying secure, as it appeared, under the protection of Pasteur's theory, seemed to be directly brought about by the action of living protoplasm until Buchner demonstrated that it, too, was the work of an enzyme present in the living yeast-cell.

No doubt, it remains in the recollection of most of my audience how this was demonstrated. In the first instance, Buchner separated the fluid contents of yeast-cells by grinding the cells with sand and infusorial earth and subsequently submitting the ground mass to very great pressure. The separated cell-juice obtained in this manner, when mixed with cane-sugar, was then found to possess the power of fermenting the sugar to alcohol and carbon-dioxide. Buchner's earlier experiments conducted in this manner were open to the criticism that residual vitality, persisting in the expressed protoplasmic matter of the cells, might perhaps effect the observed fermentation. But subsequent investigation proved that this was not so. It was found that yeast-juice can be dried without losing its fermentative power; it will also carry on fermentation in the presence of antiseptic agents which are inimical to life. Like most other enzymes also, zymase can be precipitated from yeast-juice by alcohol and still retain its power of fermenting sugar. It is unquestionable that Buchner's investigations definitely prove that the fermentative property of the yeast-cell is not directly due to vital activity, but to the activity of an enzyme—the so-called zymase—which exists within the cell. Moreover, Buchner's experiments also demonstrate that air or oxygen exerts no influence on the fermentative action of zymase. So Pasteur's noted theory that

fermentation is the effect of "life without air," can be, in its ordinary meaning, no longer upheld.

Buchner, continuing his investigations, was led to formulate the idea that alcoholic fermentation is not effected by a single enzyme breaking down sugar directly to alcohol and carbon-dioxide, but to the action of two enzymes working in conjunction, one which transforms sugar to lactic acid, and another which decomposes the lactic acid previously formed into alcohol and carbon-dioxide. The formation of lactic acid from sugar by the first enzyme was brought about, he supposed, by the sugar molecule passing through a transitional stage in which a hypothetical di-hydroxy-γ' ketonic acid was produced in some such way as is represented by the following expression



Subsequently the second enzyme was supposed to break down the lactic acid molecule to alcohol and carbon-dioxide as represented above. But the more recent investigations of Harden and Slator throw very great doubt on the view that lactic acid is formed as a transition product during alcoholic fermentation, and I believe Buchner himself no longer holds this view.

The present most interesting position with regard to our knowledge of the enzymic changes which take place during alcoholic fermentation has been reached through the remarkable investigations of Harden and his colleagues of the Lister Institute.

During a study of the properties of expressed yeast-juice prepared from yeast by Buchner's method, it was found, when the juice was subjected to rapid filtration through a Chamberland filter impregnated with gelatin, that something passed through the filter—and a residue was left behind which was no longer able to ferment sugar. On the other hand, when the portion which passed through the filter was examined, it was discovered that it also was incapable of fermenting sugar. So it was found possible to separate yeast-juice possessing active fermentative power into two parts by filtration, neither portion of which possessed fermentative power. When, however, the two portions were again united it was found that the lost power of fermentation was recovered. It became evident, therefore, that alcoholic fermentation depends on the conjunction of at least two agents—an enzyme and a so-called co-enzyme. The inactive material which does not pass through the filter, and which is coagulated and rendered powerless by heat, is regarded as the enzyme. The material which passes through the filter, and which, after heating to the boiling point, still possesses the power of activating the residue, is called the co-enzyme. Together, these two agents possess the property of fermenting sugar—apart they are both inactive.

During the fermentation of sugar with yeast-juice containing the enzyme and co-enzyme, as fermentation proceeds it was found that both these materials gradually disappear. It appears very probable that destruction of the enzyme is effected by the direct influence of the proteoclastic enzymes present in the yeast-juice; but apparently this is not the case with the co-enzyme. There is reason to believe that destruction of the co-enzyme is effected by lipase, an enzyme present in yeast-juice which decomposes fats into glycerol and fatty acids; under these circumstances, therefore, it appears possible that the chemical nature of the somewhat mysterious co-enzyme may be allied to that of the fats, but at present this should be regarded with doubt. In connection with the question of the destruction of the enzyme and co-enzyme in yeast-juice on keeping, it is interesting to note that the manner in which this takes place differs to some extent with the type of yeast from which the juice is derived. For instance, Buchner has obtained a juice from German bottom-fermentation yeast in which the co-enzyme dies out regularly before the enzyme. On the other hand, with yeast-juice derived from English top yeasts Harden finds that the enzyme and the co-enzyme are inclined to die out together.

Harden's studies of the influence of phosphates on the decomposition of sugar by yeast-juice, have also brought into prominence subjects of the greatest importance in connection with our knowledge of fermentation. When boiled yeast-juice, or a boiled solution of filtered co-enzyme is added to a fermenting

mixture of ordinary yeast-juice and sugar, a very marked increase in evolution of carbon-dioxide is evidenced in the first fifteen minutes after addition, and subsequently evolution of gas declines to its original velocity. This marked and transient rise in velocity of fermentation has been traced to the presence of phosphates in the boiled extracts employed. When phosphate of sodium or potassium was added to a mixture of yeast-juice and sugar it was found that a rapid increase in the evolution of carbon-dioxide takes place. Moreover, it was found that the phosphate acted in the manner of a chemical reagent, because the carbon-dioxide liberated is exactly equivalent to the amount of phosphate added—a molecular proportion of phosphate liberates a molecular proportion of carbon-dioxide. Further, if after addition of a phosphate to yeast-juice and sugar its equivalent of carbon-dioxide has been liberated and the fermentation rate has sunk to its normal velocity, it was found that a further addition of phosphate caused another rapid disengagement of gas, and that this condition could be repeated many times.

The next step in Harden's investigations was to ascertain what becomes of the phosphate after its addition to yeast-juice. After boiling yeast-juice mixed with phosphate, and adding "magnesia mixture" in the usual manner employed in chemical analysis to precipitate phosphoric acid, it was found that the phosphate present was no longer precipitable by the reagent—evidently it was no longer in the form of mineral phosphate, but in some other form. Further study led to the isolation from yeast-juice to which phosphate had been added, of a new compound apparently composed of a sugar (hexose) residue and phosphoric acid, to which the name "hexosephosphate" has been given. At present there is some difference of opinion with regard to the exact chemical structure of this compound, but Harden and Young consider it is formed from a combination of one molecule of hexose with two molecules of phosphate, and results in hexosephosphate possessing the formula $C_6H_{10}O_4\ (PO_4H_2)_2$. Assuming that this view is correct, Harden explains the action of phosphates when added to a fermenting mixture of yeast-juice and sugar in the following manner, presupposing of course that the action only takes place in the presence of the enzyme and co-enzyme of yeast. When the phosphate is first added, one molecule of sugar breaks down into carbon-dioxide and alcohol, and a second molecule combines with the phosphate and forms the hexosephosphate compound as represented in the following equation

$$2C_6H_{12}O_6 + 2Na_2HPO_4$$
$$= 2CO_2 + 2C_2H_6O + 2H_2O + C_6H_{10}O_4\ (PO_4Na_2)_2.$$

Whether two distinct molecules of sugar contribute, the one to the formation of hexosephosphate, and the other to the formation of carbon-dioxide and alcohol—or two fragments derived from the two different molecules of sugar unite and form hexosephosphate, has not yet been determined; but to some extent the latter view is strengthened by the extremely interesting observation that when the hexosephosphate derived from dextrose is hydrolysed by boiling with acid, dextrose is not the sugar recovered, but in the main it consists of levulose. Exactly the same observation has been made also with hexosephosphate prepared from the sugar mannose—on hydrolysing this compound, levulose is the chief product obtained.

But at present no attempt has been made to explain the complete *rôle* of phosphates during ordinary fermentation of sugar by yeast-juice. As already implied, Harden considers that the presence of free phosphate is necessary for the production of fermentation by the joint action of enzyme and co-enzyme. But, as we have already seen, after a limited time the whole of the phosphate present becomes converted into hexosephosphate, in which combination it is apparently inert. How are we, therefore, to account for the well-known regular and prolonged fermentation which proceeds when yeast-juice is in contact with sugar, if all the phosphate present becomes fixed as hexosephosphate and remains inactive? Harden finds an explanation in the presence of an enzyme in yeast-juice named hexosephosphatase, which is capable of hydrolysing the hexosephosphate into free sugar and free phosphate. The enzyme is supposed to bring about this change according to the following equation

$$C_6H_{10}O_4\ (PO_4Na_2)_2 + 2H_2O$$
$$= C_6H_{12}O_6 + 2Na_2HPO_4.$$

Consequently it follows that if the fermentation of sugar by yeast-juice proceeds in molecular proportion with the free phosphate present, that the rate at which the enzyme hexosephosphatase decomposes the hexosephosphate present, determines the normal velocity of fermentation induced by yeast-juice.

When Harden was studying the action of phosphates on fermentation, the remarkable influence they exerted naturally led him to examine the influence of arsenates, salts which

possess a somewhat close chemical relationship to phosphates.

He found, when sodium arsenate was added to a fermenting mixture of yeast-juice and sugar, that the velocity of fermentation was considerably accelerated in somewhat the same manner as if sodium phosphate had been employed. But a very marked difference observed in the case of arsenates was that no definite equivalent of carbon-dioxide was evolved during fermentation as with phosphates, and a much larger volume of gas was liberated; acceleration in the rate of fermentation also continued for a much longer period of time with sodium arsenate as compared with sodium phosphate. From these points of difference and others, Harden has arrived at the conclusion that arsenates do not take the place of phosphates chemically, but that they act in quite a different manner by stimulating the action of the enzyme, hexosephosphatase, which hydrolyses the hexosephosphate.

We have already seen in the case of yeast-juice that the velocity with which the enzyme hexosephosphatase decomposes the hexosephosphate determines the velocity with which the juice decomposes sugar. Harden considers it very probable that in the case of the living yeast-cell velocity of fermentation is controlled by the same influence, and that the main difference between the very active fermentation evidenced by living yeast-cells, as compared with the much slower action of yeast-juice, is governed by the rate at which the phosphate present goes through its cycle of change. The enzyme hexosephosphatase in its natural position, or state, within the living cell, appears to act with a much higher velocity on the hexosephosphate than when it exists in a disorganised condition in expressed yeast-juice. This is a condition which seems very likely to occur if one recognises how expression of the juice from crushed yeast-cells must mingle the enzymes present in the cells, which otherwise probably exist apart in living protoplasm within their own proper sphere of action. There are good reasons to believe that living protoplasm possesses some form of anatomy, although at present little is known about it.

With regard to the velocity of fermentation by living yeast-cells, Harden mentions that if the amount of phosphorus present in a yeast-cell and its velocity of fermentation are known, it is possible, according to the hypothesis of the transformation of hexosephosphate just mentioned, to calculate the number of times that the phosphorus of the yeast-cell must go through its cycle of change in order to produce the observed rate of fermentation. In the case of a cell of ordinary brewer's yeast fermenting sugar at 25° C., it has been determined that the whole of its phosphorus goes through this cycle twice in every five minutes.

I have mentioned before that Buchner's hypothesis regarding the formation of lactic acid from sugar as an intermediate product of alcoholic fermentation has been abandoned owing to the results of recent investigations. On the other hand, it is now supposed by some investigators that dihydroxyacetone, $CH_2OH.CO.CH_2OH$, may be an intermediate product. The evidence in favour of this is by no means convincing, but it appears very probable that a large molecule like that of glucose may break down through several stages before it is finally dissociated into alcohol and carbon-dioxide, and the possibility of dihydroxyacetone representing one of these stages is rendered more likely by the fact that glycerol is always formed in small quantity during fermentation both by living yeast-cells and yeast-juice. The formation of glycerol has never been satisfactorily accounted for, and it may well be that it takes its origin from a reduction of dihydroxyacetone

$$CH_2HO.CO.CH_2HO + H_2 = CH_2HO.CH.HO\ CH_2HO.$$

To sum up with regard to the present position of knowledge concerning the nature of fermentation. Alcoholic fermentation appears to be associated with the influence of an enzyme and a co-enzyme acting in unison on a molecular aggregation of hexose and phosphate—one-half of the hexose is decomposed into alcohol and carbon-dioxide, and the other half combines with the phosphate forming hexosephosphate, so removing the phosphate, for the time being, from the sphere of action. An enzyme, hexosephosphatase, then comes into action and hydrolyses the hexosephosphate to free phosphate and free sugar, and the cycle of change is then in a position to be again resumed.

Complex as this view of the action of fermentation appears to be, doubtless still more complex inner changes proceed during disruption of the sugar molecule into alcohol and carbon-dioxide, and many points of interest are open to future investigators before the fascinating problem is finally solved.

Before I leave this part of my subject I should like again to refer to Pasteur's original conception that fermentation is the direct result of "life without air." We have already seen that

this theory, regarded in the light of its ordinary meaning, can no longer be accepted. But if the theory is viewed in a broader sense, there is reason to believe that fermentation as a function of life may have originated from the needs of anaerobic existence. Energy necessary for the exhibition of protoplasmic activity is, in the case of ordinary air-breathing animals and plants, derived from exothermic oxidation change, or, in other words, ordinary combustion. Energy obtained in this manner was regarded as essential for the exhibition of vitality, until Pasteur pointed out that anaerobic existence was possible in the case of certain micro-organisms. How do these organisms obtain the energy necessary for their vital activity? All anaerobic organisms appear to exert fermentation changes of some kind, and all fermentation changes at present recognised are exothermic. Taking the alcoholic fermentation of sugar by yeast as an instance, it is well known, both to the technical brewer and the scientific investigator, that a very considerable amount of heat or energy is liberated during disruption of the sugar molecule into alcohol and carbon-dioxide. Presumably anaerobic yeast is capable of utilising some portion of this energy and of supporting its vital activity in this way. There is no reason apparent why energy necessary for life must be derived from direct oxidation changes, although it is usually obtained in this way. Carbohydrates, so abundantly produced by vegetable life in nature, provide a source from which energy can be obtained without the direct intervention of free oxygen if their large molecules are dissociated into smaller ones in the manner we recognise as fermentation. Is it not likely, therefore, during the course of evolution, when life appears to have adjusted itself to so many widely different conditions of being, that anaerobic life and fermentative power may together have come into existence to utilise, so to speak, the energy available in the carbohydrate molecule without the intervention of free oxygen? In this sense Pasteur's beautiful theory associating anaerobic life with fermentation may perhaps still hold good.

The origin of certain so-called secondary products of fermentation which are formed during the fermentation of sugar by yeast is a question of very considerable importance which has given rise to much discussion during past years. It has been recognised for a long time that small amounts of the higher homologues of ethyl-alcohol, such as propyl, butyl and amyl alcohols, are constantly present among the products of alcoholic fermentation, and exert an important influence on the flavour of alcoholic beverages. The quantity is always very small as compared with the ethyl alcohol produced, and the nature of the alcohols formed varies with different conditions of fermentation; but traces of some of the higher alcohols appear to be always produced during the decomposition of sugar by yeast. For many years it was considered that the source of these alcohols might be traced, not to the action of yeast during fermentation, but to the action of certain bacteria contaminating the yeast and fermenting sugar in conjunction with the yeast. In support of this view the well-known production of higher alcohols, or "fusel oil" in distillery fermentations, which are usually much contaminated with growths of bacteria and similar micro-organisms, was often quoted. This view, however, was not supported by experiment, and the question was an unsolved problem, until Ehrlich, a few years ago, demonstrated that production of the higher alcohols during fermentation originated from the action of yeast on amino acids ordinarily present in fermentable liquids. Ehrlich has shown that yeast, acting on certain amino acids, is capable of breaking them down to alcohols corresponding to the next lower acids of the series to which they belong. For instance, leucine, possessing five carbon atoms, yields amyl alcohol, possessing four carbon atoms, thus

$$\begin{matrix} CH_3 \\ CH_3 \end{matrix}\!\!>\!CH.CH_2.CH(NH_2).COOH$$

Leucine.

$$\rightarrow \begin{matrix} CH_3 \\ CH_3 \end{matrix}\!\!>\!CH.CH_2.CH_2OH.$$

Amyl alcohol.

The action of yeast under suitable conditions on other amino acids such as tyrosin, phenyl-alanine, phenylamino-acetic acid, serin, and à amino methyl butyric acid, results in every case in the expected lower alcohol being formed. The action, therefore, appears to be of a general nature, and thoroughly explains the varying quantity and character of the higher alcohols formed during alcoholic fermentation. These will evidently depend on the quantity and nature of the amino acids present, which in themselves vary with the character of the malt or other materials employed in the production of the fermentable solution.

With regard to the mechanism of this interesting action of yeast on amino acids, Ehrlich puts forward the following view:—

The NH_2 group of the amino acid is first hydrolysed under the influence of some dis-aminating enzyme, with the consequent formation of the corresponding hydroxy acid. The ammonia formed is assimilated by the yeast, and probably employed for the construction of protein matter. At the same time the hydroxy acid is subjected to what may be the ordinary zymatic action of the yeast, which dissociates it into the corresponding next lower alcohol of the series and carbon dioxide.

These actions may be, perhaps, represented as follows

$$\begin{matrix} CH_3 \\ CH_3 \end{matrix} \!\!>\! CH.CH_2.CH(NH_2)COOH + OH_2$$
Leucine.

$$\rightarrow \begin{matrix} CH_3 \\ CH_3 \end{matrix} \!\!>\! CH.CH_2.CH(OH).COOH + NH_3$$
Isobutyl ά hydroxy acetic acid. Assimilated by yeast.

$$\rightarrow \begin{matrix} CH_3 \\ CH_3 \end{matrix} \!\!>\! CH.CH_2.CH_2(OH) + CO_2$$
Amyl alcohol.

It has been definitely proved that yeast is capable of assimilating the nitrogen necessary for its nutrition from amino acids such as leucine, and this tends to confirm the view regarding the formation of the higher alcohols during ordinary alcoholic fermentation, to which I have just referred. This view also receives support from investigations of J. Effront which indicate that yeast-cells contain an enzyme "amidase" capable of liberating the nitrogen of amino acids in the form of ammonia. Effront has succeeded in demonstrating that yeast in an alkaline medium liberates ammonia from asparagin, aspartic acid, leucine, and glutaminic acid, and his conclusions have been confirmed in my own laboratory.

Another secondary product of alcoholic fermentation, succinic acid, always present in small but variable amounts among the products of fermentation of sugar by yeast, has also been shown quite recently by Ehrlich to be derived from an amino acid. In this case, however, its source is not a mono-basic amino acid, but a di-basic one, glutaminic acid. The action by which succinic acid is formed, like that by which alcohols are formed from the mono-basic amino acids, probably commences in the first instance through the dis-aminating action of the yeast, but the subsequent changes which take place are at present not properly understood.

According to the general equation representing the action of yeast on amino acids, one would expect to see γ' oxybutyric acid and not succinic acid formed during the dis-aminating action of yeast on glutaminic acid thus

$$CO.OH.CH_2.CH_2.CH(NH_2).CO.OH + H_2O$$
Glutaminic acid

$$= COOH.CH_2.CH_2.CH_2OH + NH_3 + CO_2$$
γ' oxybutyric acid.

Instead of this reaction, however, succinic acid is produced and the formation of oxybutyric acid is not recognised. Possibly oxybutyric acid may be formed and at once oxidised in the following manner

$$CO.OH.CH_2.CH_2.CH_2OH + O_2$$
γ' oxybutyric acid.

$$= CO.OH.CH_2CH_2.CO.OH. + H_2O$$
Succinic acid.

At present, however, although such a reaction seems possible, no physiological oxidation is known which is analogous, and the question is one of very many in connection with fermentation which remains for the future to answer.

A question of supreme technical importance which frequently demands the attention of the brewer, relates to the healthy development of his yeast during the fermentation process—a condition on which much depends with regard to the character of the beer he produces. So-called "yeast weakness," evidenced by restricted yeast reproduction, irregular "attenuation," and other troubles, is frequently in evidence in breweries, and the determining cause which leads to such "weakness" is often very obscure. No more difficult problem is presented to the brewer than that of yeast weakness, bound up, as it so often is, with factors influencing the life of the yeast-cell of which at present our knowledge is very incomplete. Under these conditions it appears desirable to direct attention to the trend of recent investigation with regard to the influence of minimal quantities of certain reagents on the growth of living organisms, for knowledge is accumulating in this direction which may perhaps assist in explaining some of the problems in connection with yeast weakness in the brewery which are at present very obscure.

When a vegetable organism is regarded from the point of view of its ultimate chemical composition, we find that it is constructed of some or all of thirteen elements:—C. H. O. N. P. S. K. Na. Ca. Mg. Fe. Cl. and Si. These elements exist in combination as a multitude of very various compounds, and the development and life of the organism is usually supposed to depend on the available supply of these, its component

elements. But apart from the elements just named, which ordinarily appear to be essential for the construction and life of the organism, many other elements have been found in plants. These elements usually exist in very small quantities, and often are themselves comparatively rare constituents of the earth's crust. For instance, fluorine, bromine, and iodine representing halogens, are found in plants. Fluorine in peas and barley, bromine and iodine in most marine algæ.

Arsenic, according to Bertrand's researches, is an element constantly present in both animal and vegetable organisms in minute traces. Silver is also said to be present in minute traces in marine algæ. Rubidium, cæsium, lithium, copper, manganese, zinc, boron, and a number of other elements have also been recognised in minute quantities.

The occurrence of many of these elements in plants has been known for a long time, and for the most part there has been a tendency to regard their presence as accidentally acquired by the organisms under special conditions of environment, and not as constituents essential for their existence. Recent investigations tend to show, however, that some at least of the elements present in minimal quantities may be essential to the existence of the organisms containing them.

The French school of vegetable physiologists, led by Bertrand, have, during recent years, pursued investigations bearing on this subject, and there is a growing tendency in this French school to regard the ordinary elementary constituents of living organisms as "éléments plastique" (modelling elements)—and some, at least, of the elements present in minimal quantities, as "éléments catalytique." The suggestion that the action of certain elements present in minimal quantity may be catalytic appears to originate from the recognised catalytic action of enzymes, and more especially from the catalytic action of the oxidising enzyme, laccase, the activity of which depends, according to Bertrand, on the presence of minimal amounts of manganese.

At the present time two questions of much interest and importance are being asked:—(1) Is the presence of certain of the elements found in minimal quantities in vegetable organisms, and not usually regarded as plant-foods, necessary for their existence? (2) If traces of these elements are necessary, in what manner do they act?

Some very suggestive investigations in connection with these questions have been recently published by Henri Agulhon.*

The presence of boron in minimal quantity in the ash of many plants was called attention to by Jay in 1895, but Agulhon has extended Jay's work very considerably. Agulhon concludes that all the higher plants contain boron, and in support of this view demonstrates that twenty-six different species examined, representing eighteen different orders of the phanerogams and higher cryptogams, all contained boron. He considers that the life of the higher plants may not be possible without the presence of small amounts of boron, but is unable to confirm this view owing to his inability to provide a medium of growth which is quite free from boron. He shows, however, that boracic acid in minimal doses has a remarkable effect in stimulating the growth of the higher plants. On the other hand, it appears to have no stimulating influence on low forms of plant life such as yeast and moulds.

However, my chief object just now is to call attention to some very striking work on the influence of zinc in minute quantities on plant life which has been carried out recently by Javillier, a French investigator and a pupil of Bertrand.

It has been known for a long time, from some remarkable work of Raulin, a pupil of Pasteur, that minimal quantities of zinc exercise a very favourable influence on the growth of certain moulds. In a thesis published in 1870 Raulin described the results of some investigations on the growth and development of the mould Aspergillus niger under varying conditions of food-supply which indicated that zinc, ordinarily regarded as poisonous to plant-life, was necessary for the proper nutrition of this organism. The amount required, however, appeared to be exceedingly small, and Raulin found that so little as one part of zinc in one hundred thousand of the nutritive solution in which the fungus was grown seemed to be sufficient for its needs. This old work of Raulin has been quoted frequently as instancing the marked influence which exceedingly minute quantities of reagents may exert on the growth and functions of living organisms, but in the absence of any confirmation of Raulin's work it has hitherto been accepted with some reserve. Javillier's work has now, however, amply confirmed Raulin's. Javillier, in the first instance, repeated Raulin's experiments with Aspergillus

* "Thesis," University of Paris, 1910.

niger, and found that one part of zinc in one hundred thousand of the standard nutritive solution employed by Raulin in his experiments led to an increase in weight of the fungus of nearly 300 per cent. But further experiments made by Javillier with still smaller amounts of zinc demonstrated that the minimal quantity necessary for the full development of Aspergillus niger was much smaller than the one found by Raulin. The following table shows the results of a series of experiments by Javillier, in which dilutions of zinc from 1 in 250,000 to 1 in 2,500,000 were employed.

The weights of fungus obtained with the different dilutions are given in the third column of Table I.

TABLE I.

Zinc in 250 c.c. of liquid.	Dilution 1 zinc.	Dry weight of Aspergillus.
0·0 mgm.	—	2·93 grms.
0·1 ,,	2,500,000	4·43 ,,
0·2 ,,	—	4·43 ,,
0·3 ,,	—	4·28 ,,
0·4 ,,	—	4·22 ,,
0·5 ,,	500,000	4·40 ,,
0·6 ,,	—	4·10 ,,
0·7 ,,	—	4·10 ,,
0·8 ,,	—	4·12 ,,
0·9 ,,	—	4·38 ,,
1·0 ,,	250,000	4·43 ,,

It will be noticed that the weight of fungus obtained in the complete absence of zinc, viz., 2·93 grms., rises at once to 4·43 grms. in the presence of zinc when in a dilution of 1 in 2,500,000, and that subsequently the weight of fungus remains constant in the presence of larger amounts of zinc, evidencing that a dilution of zinc of 1 in 2,500,000 is sufficient to supply all the needs of the organism.

But there is nothing in these experiments to show that even smaller amounts of zinc than 1 in 2,500,000 may not be sufficient to supply the needs of the fungus. Consequently Javillier conducted a second series of experiments with still more dilute solutions of zinc, the results of which are given in Table II.

From these experiments we see that a dilution of zinc of 1 in 25,000,000 exercises a marked influence on the development of the

TABLE II.

Zinc in 250 c.c. of liquid.	Dilution 1 zinc.	Dry weight of Aspergillus
0·00 mgm.	—	1·65 grms.
0·01 ,,	25,000,000	2·75 ,,
0·02 ,,	—	2·98 ,,
0·03 ,,	—	4·22 ,,
0·04 ,,	—	4·30 ,,
0·05 ,,	5,000,000	4·41 ,,
0·06 ,,	—	4·54 ,,
0·07 ,,	—	4·60 ,,
0·08 ,,	—	4·30 ,,
0·09 ,,	—	4·10 ,,
0·10 ,,	—	4·43 ,,

fungus, but that the amount required for its full development is about 1 in 8,000,000.

Still more dilute solutions were employed by Javillier in order to ascertain the smallest amount of zinc capable of exerting any influence on the development of the fungus. (See Table III.)

TABLE III.

Zinc in 250 c.c. in liquid.	Dilution 1 zinc.	Dry weight of Aspergillus.
0·000 mgm.	—	1·91 grms.
0·005 ,,	50,000,000	2·53 ,,
0·010 ,,	—	2·81 ,,
0·015 ,,	—	3·20 ,,
0·020 ,,	—	3·63 ,,
0·025 ,,	10,000,000	4·45 ,,

It will be seen from these experiments that the minimal quantity of zinc capable of exerting a noticeable effect on the growth of aspergillus niger is the almost inconceivably small amount of five one-thousandths of a milligram in 250 c.c. of the nutritive solution—or a dilution of 1 in 50,000,000.

How such an exceedingly small amount of substance can play a part in the economy of a living organism unless it functions in some manner as a catalytic agent, as the French school of vegetable physiologists suggests, appears very difficult to conceive. Evidence is undoubtedly accumulating which tends to

confirm the French view that in many cases minimal quantities of hitherto unsuspected agents may play a very important part in the phenomenon of life, and this view should not be lost sight of, as I have remarked before, when studying the often obscure phenomenon of yeast weakness in the brewery. It is true that Javillier's investigations demonstrate that zinc does not exert the same influence on the development of yeast as it does on Aspergillus niger, but, arguing from analogy, other as yet unrecognised chemical agents of an organic or mineral nature present in minimal quantity may play a very important part in the economy of the yeast-cell. In connection with this subject it is well to bear in mind evidence brought forward by Wildiers and others in connection with so-called "bios"—a substance the presence of which in minimal quantity is said to be necessary for yeast growth. The evidence in favour of the existence of "bios" is by no means generally accepted, but on the other hand it is not altogether disproved.

At the commencement of these lectures I said that scientific knowledge in connection with brewing had grown to such vast proportions that it was impossible to review it as a whole in many more than four lectures, and that all I could attempt in the brief time at my disposal was to select a few subjects associated with the different main processes of brewing and endeavour to treat them somewhat fully. I have tried to carry out this plan, but have felt, as my lectures proceeded, my inability to treat even the few subjects selected with any approach to thoroughness, and it must be only too apparent how much has been left unsaid with regard to the subjects I have attempted to discuss. The fact that the processes of the brewer have their origin in the complexities of life, renders discussion of any point in connection with them—however simple it may appear at first sight—many sided, and lengthy.

There is no simplicity in the processes of vitality, and the further we push our investigations into the realms of bio-chemistry, the more complex do the inner reactions of life appear. This constitutes the great difficulty of the brewer's art, but it also constitutes its great charm; it brings us into direct contact with many of the problems of life, and of necessity leads us to attempt the unravelling of some of them. It is very true that the brewer owes much to science for the progress his industry has made in recent years, but, on the other hand he can justly claim that, in return, the advance of modern science has received material assistance from investigations connected with brewing. I believe there is no other industry which can, in this respect, exhibit as good a record.

RECENT DEVELOPMENTS IN RADIO-TELEGRAPHY.*

The principal cause of the difficulties experienced to-day in maintaining satisfactory communication by means of radio-telegraphy is to be found in the phenomenal growth of this means of transmitting intelligence. The difficulties are mainly due to interference between different stations working simultaneously. Formerly the only disturbance was that due to atmospheric influences, but these are now becoming of less comparative importance, due to the great multiplication of radio-telegraphic equipments and the increasing power used in their sending apparatus. These difficulties promise to increase steadily in the future, and it is therefore a matter of some importance that we should consider the recent developments in the apparatus employed and in the principles involved.

Nearly all the developments, both in the sending and in the receiving apparatus, have had as their objective the decrease in the interference caused to, or suffered from, other stations. This is, at the present moment, of far greater importance than efficiency or even reliability.

Since the earliest experiments in radio-telegraphy, it has been sought to decrease the decrement of the train of waves which accompanies each spark. The sending apparatus in common use at the present day differs, however, but little in principle from that used with the earliest coupled aerials. The spark-gap is either stationary and provided with a powerful air-blast, or the electrodes are rotated at a high speed, thus causing movement of the air, and at the same time bringing cold metal surfaces to act as electrodes. The production of undamped or slightly damped trains of waves by means of Poulsen or Lepel arcs has not made the revolution in radio-telegraphy which was predicted, while the quenched spark between plane metal surfaces a fraction of a millimetre apart falls far short of the long open gap in reliability. The unquenched long gap necessitates very loose coupling, and therefore very low efficiency if beats in the emitted waves are to be avoided. If the coupling is made tighter than about 5 per cent., undue interference with other stations will probably ensue.

A great improvement has taken place in the nature of the note sent out by most large stations.

* Abstract of a paper read by Professor G. W. O. Howe before the Engineering Section of the British Association at Portsmouth, 1911.

In the earlier arrangements the sparks followed each other so irregularly, or the spark frequency was so low, that the signal heard in the telephone was nothing more than a crackling noise, very similar to, and easily confounded with, the noises due to atmospheric disturbances. It is not essential to tune out all other signals and extraneous noises, if the signals which have to be received have a distinctive musical note. This has led to the frequency being increased from ten or twenty to five hundred or a thousand sparks per second. The difficulty of getting, with any regularity, a thousand sparks per second with an ordinary gap and a power of several kilowatts will be apparent. If the use of a certain note became general, much of its advantage would be gone, but it would still be a great improvement in combating atmospherics.

Although the receiving arrangements have been made very convenient for rapid tuning, no radical change has been made in the detectors employed. One has still to choose between reliability and sensitiveness. If extreme sensitiveness is not desired, the magnetic detector is ideal in its simplicity. For the reception of weak signals we have the Fleming valve, the electrolytic and various crystal detectors, if necessary, in conjunction with the Brown telephone relay. Attempts have been made to obtain selective working by tuning the reed of the relay, but the general utility of the station so equipped would be greatly reduced, to say nothing of the adjustment and manipulation required.

ARCHÆOLOGY IN PERU.*

In recent years there has been much activity in the field of Peruvian archæology. At Tiahuanaco (which must always be associated with Peru, though now within the borders of Bolivia), M. G. Courtz, of the expedition of MM. Sénéchel Lagrange and de Créqui-Montfort in 1903, excavated the wide monolithic stairway which forms the eastern entrance to the great enclosure called Kalasasaya. He then dug along the western line of monoliths, and found that they were connected by a wall of cut stone. On that side he uncovered the double walls of another enclosure, and to the east he found a smaller one, constructed in similar style to the Kalasasaya, with upright monoliths at almost equal distances from each other, and a connecting wall of smaller squared stones, uncemented. From this wall projected a number of human heads, carved in the round from trachyte, and apparently portraits. Some of them are now in the Museum at La Paz. In 1910 the Bolivian Government had the Puerta del Sol set upright and cemented, and erected a shelter for the many sculptured stones which had been found. An underground chamber of carefully cut and fitted stone, discovered in 1908, is only 1 m. 40 cm. by 1 m. 30 cm. (not including five steps which lead down to it), and 1 m. 83 cm. high. The roof is of flat slabs of andesitic lava. Five colossal statues have been disinterred, of which the larger is 5 m. 72 cm. high. They are covered with finely incised designs. On the breast of one is a figure of the deity represented in the centre of the Puerta del Sol, surrounded in this case by standing personages. Another has several minute faces on its hands, and a face on each finger-nail.

Small portions of the great pyramid-building Ak-kapana can be seen—terrace walls of well-cut stone, but the masses of earth thrown out from the excavation of the centre (the present hollow is said to be more than 300 feet in diameter and 60 feet deep) hide the greater part. At Pumapanku, on the opposite side of the Indian town, a number of huge blocks of stone remain at the edge of the plateau. Although many hundreds of tons of worked stones have been removed from the ruins for different purposes, there is no doubt that systematic excavation, conducted by competent persons, would result in discoveries of the greatest interest. It is a mistake to suppose that because Tiahuanaco is at the altitude of 12,000 feet, the climate is too frigid for comfort. In the middle of winter there the early mornings are cold, and frost may lie in the shade all day, but the sun is hot and the air invigorating. Plentiful crops of barley are gathered, besides the native quinces and potatoes, and the Indians are well nourished and clothed, capable of long journeys with their lamas and other animals. On St. Peter's Day they assemble in thousands to perform their ancient dances in the town square, as described by Squier. A curious feature is that those who wear great feather crowns resembling the tops of palms, after dancing for some hours, place them in the centre of the ring and continue to dance round, bending towards the crowns as if in worship.

The amazing richness of Peru in antiquities is seen in the galleries of the National Museum at Lima, which Dr. Max Uhle has filled with the results of two years' excavation in the region of Nazca, the neighbourhood of Lima, and near Trujillo, all coast civilisations. In the bay of Ancon, the first settlements of primitive fishermen were on the side hills which slope to the sea, where the rocks are covered with shellfish. Then followed the wide-spreading town which filled the sandy area between sea and mountains, known from Reiss and Stübel's book as the Necropolis of Ancon, but now proved to have been a series of skull heaps and of reed huts, which decayed or were destroyed after the owners had been buried under them with their possessions, when others were built above. The accumulated material covers a space more than a mile square and 30 feet high. The graves are small pits lined with pebbles. Dr. Uhle spent several years in excavating at Pachacamac for the University of Pennsylvania, and has been able to form some idea of the sequence of the different kinds of

* Abstract of a paper read by Miss A. C. Breton before the Anthropological Section of the British Association at Portsmouth, 1911.

pottery from his finds there and in other places. The beautiful painted pottery at Jea and Nazca proves to be earlier on the coast than any other, and the primitive fishermen learned the art of vase-painting from the proto-Nazca folk. Richly clothed mummies, feather garments of symbolic design, mosaic ear-plugs, gold and silver cups, and a cuirass covered with small metal plates, are some of the treasures of the Lima Museum.

Of the remoter Stone Age little is yet known in Peru, but chips and scrapers are found in the alluvium on the plain of Lima, and the deposit with fragments of rude pottery, observed by Darwin, can still be seen on the top of the cliff near Bellavista.

THE NEW INDIAN FRONTIER EXPEDITION.

The punitive expedition against the Abors promises to be of a more serious character than was at first apprehended, mainly because it is directed against a semi-savage people, who have the very vaguest notion of the material power of the British rule, and who have never yet been impressed or overawed by a display of our arms of precision, such as has been forcibly brought home to the tribes on the North-West Frontier any time during the past sixty years. Moreover, the Abors are said to be able to put into the field a fighting force of from 20,000 to 30,000, armed with spears, long swords, and bows and arrows, while all the chief villages are defended by strong stockades, so that it is obvious that the somewhat elaborate preparations made by the Government of India for operations in the dense jungle-covered country inhabited by these truculent tribesmen were fully justified. The murder of Mr. N. Williamson, Dr. Gregorson, and the forty Nepalese coolies accompanying them, happened last April, and though a small force of military police was promptly got together to rescue any of the survivors, no effective advance could then be made owing to the rainy season. The present force will consist of about 2,500 men of the 8th Gurkhas, 32nd Pioneers, and a company of Sappers, with a battalion of the 2nd Gurkhas as reserve, and 500 military police with seven-pounder guns. Major-General Bower, C.B., will be in command.

The scene of the present operations lies in the hilly country intermediate between eastern Tibet and the north-eastern angle of Assam, the furthest province of British India. As far back as the seventies the Abors molested and insulted one of our political officers, and it is difficult to understand why they were not brought to book on that occasion. Our inaction was construed as weakness, and the Abors proceeded to come down to our frontier and levy toll on the Miris, and threatened to burn the sawmills at Lamirkeri. Their next step was to dispute our ownership to the country between the Brahmaputra River and the foot of the hills. Complaints arose from British subjects in these parts, engaged in elephant catching, on whom the Abors levied blackmail. With the appointment of Mr. Williamson as Political Officer in 1900, a rather more satisfactory state of things was established. He made frequent excursions into the Abor country, and amassed considerable information respecting the people, their villages, and their resources. His life was threatened more than once, but he always replied, "If you kill me my King will send, not ten men, nor a hundred men, to avenge my death, but thousands will be sent and you and your cattle and crops will be destroyed." The Abors, who had never seen more than 300 of our soldiers, were, however, incredulous and contemptuous, and it was in one of these expeditions that Mr. Williamson, Dr. Gregorson, and his party were massacred a few months ago.

A geographical problem of great interest awaits solution in connection with this expedition, this being the actual identification of the Dihang River, which joins the Brahmaputra in Upper Assam as the lower course of the great Sanpo or river of Tibet. This fact was disputed many years ago by the famous geographer, Klaproth, who contended with much elaboration that the Sanpo flowed out further east into the upper Irrawaddy. The gradual development of geographical knowledge from the Indian side has made it practically certain that the river known in Assam as the Dihang can be none other than the Tibetan Sanpo. The last explorer was an agent of the Indian Survey Department named Kinthup, who was commissioned by Captain Harman in 1880 to descend the Sanpo from the Tibetan side and cast a number of specially marked wooden logs into the stream, watchers being posted at the mouth of the Dihang in British territory to note if these logs were duly floated down. The endeavour proved unsuccessful, but Kinthup collected some useful topographical information, and claimed to have followed the Sanpo in its southern bend or elbow to a point thirty-five miles from the British frontier. If correct, this would seem fairly conclusive on the point of identity. At the time of the Younghusband expedition to Tibet, some pressure was brought to bear on the Indian Government to permit a small exploring column to return from Lhasa to India by way of the Sanpo River, but fear of the Abors induced the Viceroy to withhold the necessary sanction for that expedition. Without the co-operation of another column from the Assam side such an undertaking might clearly have been risky. On the present occasion, however, exploration and reconnaissance are a military necessity, and we may fairly conclude that the unknown section of the river will be surveyed from the Tibetan to the British frontier. This will include the celebrated falls of the Sanpo, which may be said to mark the spot where the river bursts through the chain of the Himalayas in its descent from the plateau of Tibet to the plains of India.

HOME INDUSTRIES.

The Cardiff Strike.—How easy it is for workmen to injure themselves, even when their demands have been granted, is shown by the seamen's strike at Cardiff. The number of unemployed sailors in the port of Cardiff at the present time is extraordinarily large, and it is so as a direct result of the strike in which they were the apparent victors. For the exceptional number of the unemployed is due to the action of the seamen's leaders in demanding under the recent Agreement a *minimum* wage of £5 per month, whereas the prevailing wage in most other ports is £4 10*s*. To avoid being penalized 10*s*. per month per man the Cardiff shipowners are signing on their crews elsewhere. On the other hand, many seamen have flocked to Cardiff from other ports in the belief that by so doing they would be able to secure higher wages. It is now said that the leaders of the men are inclined to accept the view that the wage secured by the Agreement is too high, but unfortunately it provides that there shall be no alteration in the port wage rate until three months' notice has been given by either side.

The 1889 Strike.—It has been generally believed that the London Dock strike of 1889, in which the present President of the Local Government Board figured so prominently, resulted in a great victory for the men, but it may well be doubted if, on the whole, they were any gainers by it. A correspondent of *Fairplay*, who for years held a prominent position in the labour department of the Millwall Dock Company, submits some facts which suggest that the men lost rather than gained by the strike. Prior to it, in 1889, the dock men were paid at the rate of 5*d*. per hour, and the recognised day was 8 a.m. to 6 p.m., with nothing deducted for meals; so that the men received pay for the full ten hours, making their day's money 4*s*. 2*d*. They struck work in August 1889, for 6*d*. per hour. After being out of work for a month, they got it, but on the condition that they would not be paid for the dinner-hour as heretofore. Thus their money, if they worked up to six o'clock, would be 4*s*. 6*d*. instead of 4*s*. 2*d*. After the strike the masters made the day eight to five instead of eight to six, the hour between five and six being an unprofitable one, as very little practical work was performed. As under the new agreement the dinner-hour was deducted, the men only received pay for eight hours at 6*d*., being 4*s*., against 4*s*. 2*d*. previously. Nor was this the only way in which they suffered. The labour employed was reduced to a minimum, and the men chosen were more severely looked after, with a view to getting the best work out of them, and as a consequence of the strike an immense amount of work was lost to the Port of London, and went away to Antwerp and other foreign ports, which has never been recovered. The men were the sufferers on all points, and the strike saddled them with the cost of maintaining an expensive union. It left the men worse off than it found them, and it has yet to be shown that the recent revolt will be of any greater permanent value to them.

The Whisky Trade.—When the duty on whisky was raised to 14*s*. 9*d*. per proof gallon it was believed that it would seriously check consumption, and for a few months it did so, but the effect seems to be passing away. Up to the time of the increase in the duty the consumption of Scotch whisky was progressive, and in the first six months of its operation the reported turnover declined about one-third, but the visible consumption now begins to show signs of improvement, and the returns have gradually improved. In 1905, stocks amounted to no less than 121,778,000 gallons, or about five years' consumption at normal rate, but since then they have declined somewhat, and one effect of the reduction has been to reduce the accumulations of old matured malt whisky, whilst the reduced make of recent years has sensibly lessened the quantities of young grain whiskies required for blending purposes. But now an increased demand has arisen for these whiskies, to make up for the growing deficiency in the stocks to meet the requirements of blending, which have been hurried into the market to secure young whisky for trade purposes before speculators drive up the prices too high for profitable trade. The result is that the younger makes of whisky in bond have risen much above the prices current a year ago, while old grain whisky is half as dear again. The rise in the price of maize, too—the chief raw material of the grain distiller—has been considerable, and is likely to continue. If it does there must be further rise in the price of new grain whisky, and the continued activity of the distillers, both grain and malt, may safely be predicted.

The Harvest.—One feature of the 1911 harvest is its earliness, and the quickness of its gathering in. Begun in Wiltshire on July 18th, it was over nearly everywhere in England by September 2nd, and in the Home Counties by August 19th. It would be strange if, with the weather we have had, the wheat crop was other than first-rate, for there was a favourable preparation for the germinating time, an adequate rainfall to sustain growth between the beginning of March and the end of June, and since then a period of almost unbroken heat and sunshine, with high temperature by night as well as by day. Accordingly the quality of the wheat is as good as that of the 1910 crop was bad. It is nearly all up to the miller's standard, is fit for immediate milling, and needs very little admixture of foreign corn, and the yield will be above the average, although there is considerable variation in different districts. The new barley crop is estimated at 86·67 per cent. of a full crop, which is the lowest estimate since 1903, and five points below the average of the previous ten years. Taken as a whole, oats are the worst of the cereal crops, but in some districts they are exceptionally good,

as in Norfolk. Taking the average of the cereal crops, the *Times* puts it at 83·7, the lowest average for the last fourteen years, with the exception of 1905, when it stood at 83. The hay crop was of exceptionally good quality but short in quantity, and in many counties there has already been resort to hay-ricks. Roots, it need hardly be said, are in sad plight, even mangel-wurzel being very small. As to swedes and turnips, in many places they have practically disappeared. Hops are good in Kent, and in some districts of better quality than for many years. Hereford reports a small crop of good quality. The Gloucestershire hop cultivation has almost disappeared, and the total acreage under it continues throughout England—the only part of the Kingdom where hops are grown—to diminish rapidly.

Retail Prices.—There is general complaint at the rise in food prices, but it is not very easy to see how these rises, or most of them, can be justified, for they are not to be reconciled with market quotations. Flour should be the best guide to the price of bread, but figures given by the *Mark Lane Express* show that the price of September 1910 has never since been reached, while in each quality there has been a decline as compared with a year ago. Yet the average price of bread has risen. Take again meat. The same authority gives tables of the prices of cattle and sheep at the Metropolitan Market, Islington, which show that, so far from there being a rise in the price of cattle, there has been a decline in three classes as compared with a year ago, and no change in the other two. And it is almost precisely the same with sheep. Yet meat is dearer. And so with poultry and eggs. The price of poultry, balancing one variety with another, is much the same as a year ago, and eggs are cheaper. Bacon is another commodity that costs the consumer more than it did a year ago, but the market price of Irish bacon, the only kind quoted, has fallen in price.

The Flax-mill Dispute.—Reference was made in these Notes last week to the flax-mill dispute at the Broughton flax-mill, where the women and girls struck for better wages. The dispute has now been settled and the strikers have returned to work, the employers having made substantial concessions. The settlement is a compromise. The workers have not got all they asked for, but they have got a good deal. Men, women, and girls alike are substantially bettered. The bonus system has not been got rid of, but whereas before the strike, if only one day were lost in the week there was no bonus that week, and in the case of the reelers, if only a quarter day were lost the bonus went, the new conditions are more favourable. And the concession of a minimum wage of 20*s*. a week to the labourers is a substantial gain. The pity is that these readjustments of wages are not brought about without strikes.

Cotton Supplies.—It would seem that the expectation of a bumper American cotton crop—a crop of 14,000,000 bales—must be abandoned. At the end of July the average condition was given as 89·1, the highest for the time of year since 1894, but the United States Agricultural Department's report for August shows a drop of 15·9 to 73·2, the greatest August depreciation since 1902, when it was 17·9. For some years the condition figure at the end of August has been a fair index of the size of the coming crop, but much depends upon September. It was hoped that the crop this year would be the highest on record. That is no longer likely, but with a good September it may exceed that of last year, namely 12,120,000 bales, and may reach 13,000,000, seeing that there is this season an increase of acreage which will probably bring something like an additional half million bales. It is a little curious, by the way, that the weather and crop reports during August did not indicate the great deterioration recorded by the Agricultural Department.

CORRESPONDENCE.

THE PEA-NUT.

The valuable paper in the *Journal* of this date, on the "Pea-nut" industry of Marseilles, is defective for its many Anglo-Indian readers in not stating that the "Pea-nut" is their "Earth-nut," "Ground-nut," and "Manilla" gram ["gram" = *Cicer arietinum*, the "Chick-pea"], the *Arachis hypogæa* of Linneus, known to the natives of India by the names of *mung-phali* ["*Phaseolus Mungo*-fruit"], *bhui-chana* ["Earth-gram"], *chini-badam* ["Chinese-almond"], and *vilati-mung* ["Foreign-*mung*"], etc., etc.; this leguminous plant, although now cultivated over all India and the East Indies, from Abyssinia to China, being a native of South America; and one of the numerous economic plants of that continent introduced, through the intermediation of the formerly puisant Portuguese into Africa and Asia; one of the greatest services rendered by any nation to humanity at large, but for which they never get any credit in the standard histories of Portugal.

For tastefulness the "Earth-nut," or "Pea-nut," may be classed with the "Cashew-nut," and the "Pistachio-nut," the *Pistache de terre* of the French; but all three are most indigestible. The oil, in salads, is a good enough substitute for olive oil; but both olive oil and "Pea-nut" oil are inferior in delicacy of smell and taste to almond oil; while almond oil itself must yield the palm for purity of savour to Sesamum oil, the product of *Sesamum orientale*, or *indicum*, of Linneus—the *tila*, that is "the oil," *par excellence*, of India; which from the first dawnings of human history in the valleys of the Tigris and Euphrates, and the Nile [Semitic *sim-sim*, Hebrew *semen* = "oil" generally, Arabic *al-jul-jul-an*, our "Gingelly," Greek *σήσαμον*, etc.], has been used throughout the East for food, both in the grain and

the oil pressed from it, and the oil also for lighting purposes: this latter use of it having given rise to the phrase:—"Open Sesame!"—meaning, simply, as we should say, "Strike a light," "Bring a candle," "Open up the darkness." "Open Wheat!" "Open Rye!" "Open Barley!" were of no avail, and only when Kasim cried "Open Sesame!" was the treasure in "Ali Baba and the Forty Thieves" revealed. I was the first to point this out in the first edition of my official "Catalogue of the Economic Botanical Products" of the Government Central Museum, afterwards [1857-8] enlarged into the Victoria and Albert Museum, Bombay. Cotton and Sesamum are the two most reliable crops in all India; and the proverb runs throughout Southern India:—"When a failure [of the harvest] is feared, at once sow Sesamum."

Along the Concans coast of western India the household illuminant used by the fisher-folk is a fish through which a wick is drawn, and, as required, lighted; and it is remarkable that the brazen lamps used in the temples of the Concans, and up, over the *ghats*, in the valleys on their Deccan slopes, is formed on the longitudinal section of a fish, head and tail and all, with a cup-like hollow, below its belly, to serve as a pedestal, and hold the oil, the wick being drawn out into its head.

September 8th, 1911. GEORGE BIRDWOOD.

GENERAL NOTES.

MILITARY AVIATION IN ITALY.—The new aerodrome at Aviano, which will be the largest in Europe, covers an area of upwards of 12,000,000 square metres (nearly 3,000 English acres) in the communes of Aviano, Rovereto in Piano, San Quirino and Pordenone, near Udine. The twelve hangars will contain sixteen aeroplanes of the Farman and the Blériot types, most of which have been built by the mechanics of the specialist brigade of aviation. Two aeroplanes of the Etrich type, recently purchased at Vienna, and a Newport machine made in France, are also ready for use. Workshops and accommodation for the men of the brigade are also provided. The aerodromes at Bovolenta and at Gallarate are now ready. The workshops for the construction of aeroplanes at Centocelle (Rome) have now been transferred to Gallarate. The three establishments are under the command of Colonel Montezemolo, the director of military aviation.

THE FISH INDUSTRY OF THE PHILIPPINES.—The latest fishery enterprise in the Far East has been the canning of sardines and anchovies in the Philippines. At the recent fair held in Manila were displayed fifty cases of sardines put up by the Bureau of Science of the Philippine Government. The fish were packed in peanut-oil of Philippine production, with the usual spices, in oval tins furnished for the experiment by local Chinese tinners. The fish were first salted and cleaned, soaked in brine, and washed to remove the scales, dried in the open air, boiled in oil, drained off and packed. The tins, after being soldered, were immersed in boiling water for two hours. This simple process produced a fair grade of packed fish. The peanut-oil can be had in large quantities at comparatively low prices. The supply of sardines and anchovies in Philippine waters is said to be very large. Sufficient of these fish are said to be caught in Manila Bay alone to supply a factory catering not only for the needs of the Philippine Islands in the way of packed fish of this grade, but for a considerable export trade as well. The Philippine species of sardines and anchovies are reported to be delicate little fish of exceptionally good flavour and fair size, and compare favourably in all respects with similar fish in all parts of the world.

THE SPANISH WINE INDUSTRY.—The world's output of wine amounts to about 3,700 million gallons, of which one-seventh, or 500 million gallons, was produced by Spain in 1909. To this should be added about thirteen million pounds of dry grapes exported to France and Italy, representing 20,000 tons of fresh grapes, which, at the low rate of one hundred gallons of wine to the ton, would represent two million gallons of wine. Spanish wines are divided into red, yellow and white, and each of these again into dry and sweet. They are all native wines, produced by natural fermentation, without any adulteration. Only a little blending is done for the sake of their colour, aroma and flavour. Dry wines do not contain more than 2 to 5 per cent. of alcohol; sweet wines 10 to 12 per cent., and seldom more than twenty per cent. In the fermentation of the wines no sugar is added. The vines are grown on clay soil, which contains both iron and lime. An acre of land frequently yields as much as five hundred gallons. The wine most exported from Spain is the ordinary red wine in pipes or casks.

THE SILKWORM INDUSTRY IN KOREA. — The Japanese have recently been advertising in the district of Antung for fifteen hundred Chinese cocoon experts to promote silkworm breeding in Korea. It is thought that the silkworms of Manchuria will thrive in the northern part of Korea, as the climate in the two countries is similar. The Japanese have therefore bought about one million cocoons from the Chinese at fancy prices, and commenced their experimental work in June, 1911. The Manchurian silkworm is a valuable variety, and produces a thread which is very thick and strong. This is largely due to the severity of the winters, which causes the silkworms to spin a cocoon heavy enough to withstand the cold. Unlike most other silkworms also, the Manchurian variety feeds upon the oak trees which are abundant in the district of Antung. As the same kind of oak is found in the northern portion of Korea, the new industry is, it is said, likely to become one of the most important in that part of Japan's recently-acquired territory.

᠎# Journal of the Royal Society of Arts.

No. 3,070. VOL. LIX.

FRIDAY, SEPTEMBER 22, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

THE ROYAL SOCIETY OF ARTS.*

By Sir Henry Trueman Wood, M.A.,
Secretary of the Society.

III.—The Society's Offices.

The first permanent offices of the Society were in Craig's Court, Charing Cross. At a meeting held on February 19th, 1755, at Peele's Coffee House, arrangements were finally made with Shipley that he should take a house in Craig's Court, and sublet a portion to the Society. Whether the rest of the house was used by Shipley for his Academy or not, there is nothing in the Minutes to indicate. The rent paid was £20 a year, including coals and candles. The first meeting at Craig's Court was held on March 1st, 1755. Here the Society remained for a year, but the rooms were too small, so they moved to a house at the corner of Castle Court on the east side, "opposite the New Exchange," on June 2nd, 1756. For this they paid to John Fielding a rent of thirty-five guineas for the first floor and some other part of the house. Castle Court was a narrow alley leading from the Strand to Chandos Street. It disappeared when the district was rebuilt in the reign of William IV., the date being commemorated by the names of King William Street and Adelaide Street. The ground on which the house containing the Society's offices stood now forms part of the site of the *British Medical Journal* office.

The accommodation, however, soon proved insufficient for the growing needs of the Society. It was increasing rapidly in numbers and in wealth, and it soon seems to have felt the need of more spacious quarters. Two years after it was established in Castle Court, we find in the Minutes that inquiries were being made for new premises. Several localities were suggested and rejected. In May, 1758, a committee reported favourably on a proposal to acquire Exeter Change. It appeared that a total outlay of £2,500 would have been required for necessary repairs and alterations, and that Lord Exeter was willing to grant a lease for about sixty years at a rent of £200 a year. As a set-off against this, there was the rent of certain shops forming part of the building, and to be sub-let by the Society. The outlay, however, was considered too great, and the proposal was declined.

Eventually the Society came to terms with Messrs. Williams and Woodin, who carried on the business of upholsterers and carpenters in premises opposite Beaufort Buildings in the Strand. These premises included the house afterwards No. 380 and 381, Strand, and a warehouse and yard behind. Messrs. Williams and Woodin agreed to build a Great Room for the Society on the site of their warehouse, and to let this room, with another good-sized room on the ground floor, together with a certain part of the house, for a payment of £200 and a rent of £120 a year for three years, and £100 afterwards, for a term of fifteen years from Midsummer 1759. The first meeting in the new rooms was held on July 18th in that year. The various alterations in, and additions to, the buildings were made under the superintendence of Mr. (afterwards Sir William) Chambers, who acted as the Society's architect. He later achieved a great reputation, his best-known work being Somerset House.

It has not been found possible to make out precisely how much of the Strand frontage was occupied by the Society. They certainly had an entrance on the Strand, and perhaps they had the whole or part of the first floor. Or the original house may have been divided into two, and this idea is suggested by a comparison of the entries in the sewer rate-book for 1763 and subsequent years. The earliest entry shows one house, in the occupation of Thos. Wooden [*sic*]; the entry for 1765 shows the same house as

* The previous articles of the series appeared in the *Journals* of June 9th and 16th.

occupied by Geo. Box (in whose name the lease to the Society had been taken out) and formerly by Price, while subsequent entries show two houses. It was certainly for long in the joint occupation of the Society and the landlords, for both Williams and Woodin, who were members, have their addresses recorded in the lists as "Society's Offices."

The house stood on ground which was then part of the property of the Duke of Bedford, and had been leased by him in 1753 to John Price, by whom it was demised to Williams and Woodin. It was, when let to Price, the "Greyhound Tavern," but presumably Price or his successors gave up the tavern and used the premises for other purposes. The district extending a certain way eastwards from Southampton Street is designated in the rent-books of the Bedford estate "Fryers' Pyes," but up to the present it has not been found possible to ascertain the meaning of this curious title or to find any explanation of it.

For the information which has enabled the site of the Society's old offices to be identified, the writer is entirely indebted to Sir Laurence Gomme, the accomplished Clerk of the London County Council, and to Mr. A. R. O. Stutfield, the steward of the Bedford estate. Both these gentlemen have taken a great deal of trouble in hunting up obscure details in the records under their respective charges, and the writer has much pleasure in acknowledging the valuable and ready help they have given. It has always been known that the Society occupied offices "opposite Beaufort Buildings" from 1759 to 1774, but it had been assumed that these offices were at the north-east corner of Beaufort Buildings, in the house afterwards No. 96, Strand, long well known as Rimmel's, the perfumer's.

This, however, is undoubtedly a misapprehension, and it may be taken as quite certain that the building occupied by the Society was either on the ground now covered by the western wing of Haxell's Hotel, or partly on that ground, and partly on what is now Exeter Street. Exeter Street was originally a *cul-de-sac*, extending west from Catherine Street. The L-shaped extension, leading southwards into the Strand, was not added until much later. In all probability this limb of Exeter Street passes over and occupies the western side of the Great Room built by Williams and Woodin for the Society on the eastern side of the narrow alley then known as Little Denmark Court. The west side of this court is apparently coincident with the west side of the present Exeter Street.

All this district was altered under the Act (7 Geo. IV. cap. 77) passed in 1826 for the widening of the Strand, and in the various improvements carried out Exeter Change itself disappeared. Beaufort Buildings remained until 1902, when the extension of the Savoy Hotel swallowed it up, and all the old buildings on this part of the south side of the Strand disappeared. The courtyard of the hotel now occupies the ground which was formerly the roadway of Beaufort Buildings.

If the conclusions drawn from an examination of the plans and documents in the Bedford estate offices are correct, the "Great Room" was worthy of its name, being an apartment 80 ft. long by 40 ft. broad. It was here that the first exhibition of pictures by British artists was held in 1760. There was also a smaller room, 40 ft. by 20 ft., on the ground level, in which the first exhibition of models and machines was held in 1761.

A considerable amount was expended in fitting and furnishing the rooms and offices, besides the cost of structural alterations. Among other improvements it was found necessary to make a "crossing" in the Strand, at a cost of three and a half guineas, to facilitate the access to the Society's entrance door.

A year and a half later, in January 1761, some additional premises were taken by the Society from Woodin (Williams died in 1760, and his interest was acquired by Woodin), to be used as a residence by Dr. Templeman, the newly-appointed secretary. The description in the lease is not sufficient for them to be identified with certainty. They may have comprised a house adjacent to the Great Room and looking into Bennet's Court.

In 1770, the lease of the Society's premises having nearly expired, and the accommodation being again found insufficient, it was decided to advertise for new premises, and accordingly an announcement was inserted in some of the daily papers inviting any person who had proposals to make for the accommodation of the Society to communicate with the secretary.

The result of this advertisement was that the Brothers Adam, who were then occupied with their scheme for the construction of the Adelphi, offered to include in that scheme a suitable house for the Society's purposes.

The history of the Adelphi has often been

written.* The site was long occupied by the historic buildings of Durham House, the residence of the Prince-Bishops of the northern See. The house and grounds originally occupied the area between Adam Street and Buckingham Street, from the Strand to the river. The New Exchange was built in 1608 by Lord Salisbury on the site of the Durham House stables, and extended from George Court to what used to be Durham Yard, but is now Durham House Street. It thus included the site of Coutts's old Bank. It was pulled down in 1737, when shops and houses were erected along the present line of the Strand. In the space between these buildings and the river, where old Durham House once stood, fronting the river, with its gardens reaching to the Strand, were "a number of small low-lying houses, coal-sheds and lay-stalls, washed by the muddy waters of the Thames." The ground sloped down from the Strand level to the brink of the river, which must have been, at high water, somewhere about the inner edge of the Embankment Gardens.

Adelphi Buildings.

On this slope the Brothers Adam (Robert, William, James and John) proposed to build a great terrace, level with the Strand, the idea being taken from the arched terrace or gallery in the Palace of Diocletian at Spalatro,* which Robert Adam studied with great care, and described in a monumental folio.† The ground was in the possession of the spendthrift Duke of St. Albans, or rather of his trustees. By the year 1642 the estate had finally passed out of the possession of the Bishops of Durham, and under the provisions of an Act of Parliament it became the property of the Earl of Pembroke and Montgomery, a rent-charge only of £200 a year being reserved to the See of Durham. This rent-charge, it may be interesting to mention, is still paid by the present owner to the Ecclesiastical Commissioners. In 1677 the estate was sold by the Earl of Pembroke to Sir Thomas Monpesson, and in 1716 it was again sold by the representatives of Sir Thomas Monpesson to the trustees of the will of Sir John Werden, whose daughter Lucy married Charles, the second Duke of St. Albans. Their son George, the third Duke, brought the estate into settlement, and in 1767 a private Act of Parliament was passed for vesting part of his

* The fullest history of the Adelphi is contained in three articles by Mr. H. B. Wheatley in the *Antiquary* magazine for June, July, and September, 1884. In these a great deal of information will be found which it has not been thought needful to include here, as it has no special connection with the Society of Arts. Mr. Austin Brereton's "Literary History of the Adelphi" (1907) is the most recent book on the subject. Mr. Percy Fitzgerald devotes the best part of a chapter of his "Picturesque London" (1890) to the Adelphi.

* Fitzgerald, "Picturesque London" (1890), p. 39.

† "Ruins of the Palace of the Emperor Diocletian at Spalatro in Dalmatia," by R. Adam, F.R.S., F.S.A., 1764.

estates in trustees for the purpose of raising money to pay his debts.

These trustees, Lord Charles Spencer and Sir Philip Musgrove, in 1768 granted a lease to the Brothers Adam for ninety-nine years at a rent of £1,200 a year. It has seemed worth while to record these details because they have never been accurately stated in previous accounts of the Adelphi, and it is only by the obliging assistance of Mr. George Drummond, the owner of the Adelphi, and of Messrs. Fladgate, the solicitors to the estate, that it has been possible to trace out the manner in which this historic bit of London passed into the possession of its present owner.

The design proposed by the Brothers Adam was duly carried into effect, the requisite height on the river side being obtained by the construction of tiers of superimposed arches.* Some of these arches formed public thoroughfares, and later gained an unenviable reputation on account of their nocturnal frequenters. Others were let as storehouses; at one time a number of cows were stabled in some of the arches, and supplied milk to a large part of the West End. Others again served as cellars for the houses built on the substructure. The Society's house has two stories of cellars below the south-western part of the building, while the foundations of the north-east corner are in the original ground.† The whole work has undergone a certain amount of repair, a good deal of strengthening and reconstruction having been carried out about the time of the termination of the original lease, when the Thames Embankment was made;‡ but it seems now as sound as when it was first built.

The work, commenced in July 1768, was practically completed in about six years, but before it was finished the Adams were in financial difficulties. In the course of their operations they encroached on the foreshore of the Thames, and thereby involved themselves in a dispute with the Corporation, their difficulties being increased by the political circumstances of the time, as the Corporation were strongly Wilkesite, while the Adams enjoyed Court favour. Eventually they succeeded in obtaining an Act of Parliament to authorise their proceedings. In this they were assisted by their patron, the Earl of Bute. Their pecuniary difficulties were set right by means of a second Act, which empowered them to organise a lottery, the chief prizes in which were the houses then in course of building on the estate. In many cases the prize-winners sold their rights, and thus the sub-leases became the property of various owners. Their tenures expired at the termination of the principal lease in 1867, long before which time (in 1787) the property had come into the possession of the Drummond family. George, the third Duke of St. Albans, had no son, and was succeeded as fourth Duke by George Beauclerk, the grandson of Lord William Beauclerk, the second son of the first Duke, who had married (in 1744) Charlotte, the other daughter of Sir John Werden above mentioned. Lord William Beauclerk's daughter Charlotte married John Drummond, the son and successor of the Hon. Andrew Drummond, the founder of Drummond's Bank, and to her the Adelphi estate was devised by her nephew, the fourth Duke. From her son George the estate passed to his son, his grandson, and his great-grandson, George James Drummond, the present owner of the estate and the Society's landlord.

John Drummond and his cousin Robert were among the earliest members of the Society, and the connection of the family with the Society has since continued.

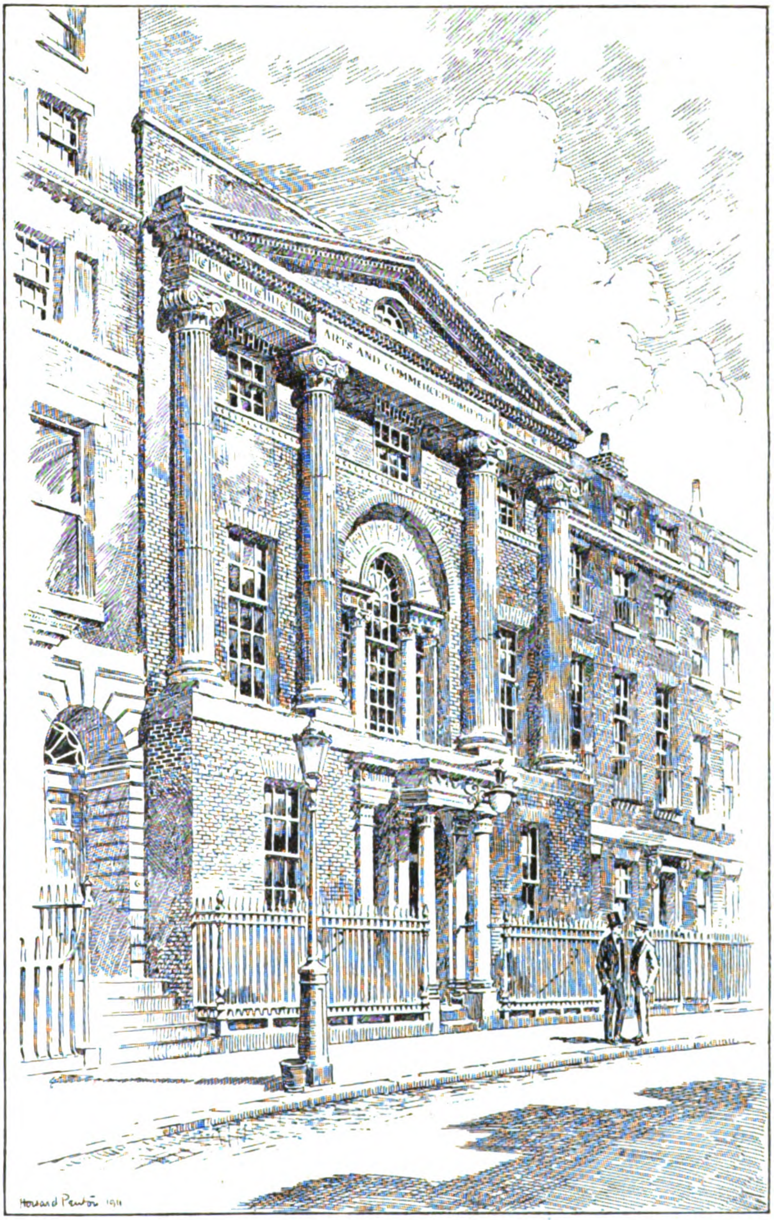
Negotiations, the progress of which is described, though not very fully, in the old Minute-books of the Society, went on for some time, and eventually the Adams undertook to build a house such as was required for a premium of £1,170, and a rent which was finally settled at £200 a year. The plans, after much discussion, were finally approved, the foundation-stone was laid by Lord Romney in 1772, and the Society entered into possession in 1774, though the lease only dates from 1775. It was for 91½ years, from Midsummer 1775, ending at Christmas 1866—a quarter before the end of the landlords' lease.

Such was the origin of the historic building in which the Society has carried on its work for 135 years. It really consists of two houses, one of which was intended for the private residence of the secretary. There has always been a communication between the houses on the ground and first floor (as well as in the basement),

* The view of the Adelphi (p. 1011) shows the Terrace with the houses as originally built, and justifies Horace Walpole's criticism (quoted by Mr. Wheatley) that the Adelphi buildings resembled "warehouses laced down the seams, like a soldier's trull in a regimental old coat." There are still two or three houses in the Adelphi which preserve this old form of decoration—long vertical mouldings extending from the ground to the uppermost story. The illustration is from a contemporary print.

† The view of the front of the building is from a drawing by Mr. Howard Penton. It shows no changes since the house was built.

‡ The Embankment was commenced in 1862 and opened in 1870.



THE SOCIETY'S HOUSE, A.D. 1911.

and recently a third one was constructed on the second floor. Otherwise the two houses are separate and distinct. The last secretary to live on the premises was Sir George Grove.

No structural alterations of any importance seem ever to have been made in it. In 1815 the old skylight in the meeting room was altered, the existing lantern being substituted for the original oval light. The position of the platform and the chairman's seat in the meeting room were altered in 1863, when certain repairs were carried out in connection with the grant of a new lease (for thirty years), dated Lady Day, 1867. Originally they were on the north side of the room, facing the entrance. They are now on the east side. The reason of the change was to give greater facility of access from the offices to the officials' seats. The old arrangement was inconvenient in this respect, but in all other respects it was certainly better.* The present decorations of the ceiling, which were designed and executed by Messrs. Crace, are of the same date. At the same time the existing glass cases in the lower room—which was originally designed for the "Repository" of the Society's collection of mechanical inventions—were substituted for the pillars which previously gave apparent support to the ceiling and to the floor of the room above. This change had nothing to recommend it, and should never have been made. The appearance of the room as it was originally designed was much better, and the present cases are at once ugly and useless.†

In 1847 the mosaic pavement in the entrance hall was presented by Messrs. Minton (then Minton and Blashfield); it is interesting as being one of the earliest examples of the application of mechanically produced tesseræ under Prosser's patent, afterwards the foundation of an extensive industry. The glass mosaic on the staircase was laid down in 1874 by Messrs. Powell. This, again, was one of the first uses of a novel and ingenious method of manufacture, though it had previously been utilised in one of the staircases of the South Kensington Museum. In 1877 the existing heating apparatus was introduced. Previously the meeting room had been very inefficiently warmed by furnaces in the basement, the heated air from which passed through gratings into the library, and thence by other gratings into the meeting room. In 1882 electric light was first installed. The current was obtained from a Siemens dynamo driven by a gas-engine, both being placed in one of the cellars. Later a storage battery (E.P.S.) was added. The cost of the installation was met by a subscription from past and present members of the Council. In 1899 this private installation was given up, and the current was taken from the then newly-established street mains. The above account is believed to include practically all the alterations of any importance since the original building of the house.

In 1774, when the Society was about to move into its new house in the Adelphi, the question of the decoration of the Great Room naturally gave rise to a good deal of discussion. It was determined that it would be desirable to procure "proper historical or allegorical pictures," to be painted by the most eminent artists. Further, it was decided that there ought to be eight historical and two allegorical pictures; that the subjects of the historical pictures should be taken from English history, and that the allegorical pictures should be "emblematick designs relative to the Institution and views of the Society." A proposal was accordingly made to eight artists, that they should paint each a historical picture, and to two others that they should paint allegorical pictures, the conditions being that they should not be paid, but should receive the profits arising from an exhibition of the pictures, to be held for four months. The historical painters were Angelica Kauffman, Sir Joshua Reynolds, West, Cipriani, Dance, Mortimer, Barry, and Wright; the allegorical painters, Romney and Penny. Mr. Valentine Green, the engraver, was requested to communicate with the selected artists, and to report their answer. Unfortunately, the answer—mainly, it appears, owing to Sir Joshua Reynolds—was a refusal. The portraits of the first two presidents of the Society, Lord Folkestone and Lord Romney—the first by Gainsborough and the second by Sir Joshua—were placed over the two chimney-pieces, and there the matter rested for a while.

Three years afterwards, viz., in 1777, Barry authorised the same Mr. Green—a member of the Society who took a very active interest in its welfare, and who afterwards received a gold medal on that account—to inform the members that one of the Royal Academicians they had applied to was willing to take the whole work upon himself, and to decorate

* The illustration shows the arrangement of the room in 1804. It is copied from a print in the Crace Collection, now in the British Museum.

† The picture (p. 1017) of the "Model Room," or "Repository," is copied from a print in Knight's "London" (1843), and shows very well the difference between the room as it now is and as it was originally built.

the Great Room "with a series of pictures analogous to the views of the Institution." It was estimated that the canvas, frames, and colours would cost £100, and there was a further expense of £30 for models, which the artist offered to discharge, but which was eventually paid by the Society. The proposal, made at an ordinary meeting of the Society, was referred to the committee of "Polite Arts." The committee considered and accepted it before it was known who the artist was to be, and thereupon the chairman produced a letter from Barry, stating that the offer was his. Barry was then young and little known, full of confidence in his own powers, and assured that nothing but opportunity was wanting for him to make a reputation. Nor were his objects wholly personal. He was impressed—as well he might be—with the degraded condition of English Art, "fitted for nothing greater than portraits, and other low matters, from whence no honour could be derived either to the artist or the country"* and he believed that the production of "some great work of historical painting" would refute the assertions of those foreign critics who declared English painters to be incapable of any permanent work, and would also serve as an example to his countrymen. Feeling at once the necessity of the work, and the capacity within himself for executing it, he set himself to do it, without, as it seems, considering or caring even how he was to live during all the years so long a task must occupy.

On the whole, his hopes of fame were realised, for such reputation as Barry now possesses rests entirely on the great pictures he painted for the Society. The man himself was of a strange character, his life was by no means happy. An artist of considerable power, his powers were yet not equal to his own estimation of them; and his life, like that of Haydon, a few years later, was embittered by what he considered a lack of appreciation of his deserts.

He was born at Cork in 1741. The ability he showed in various early pictures gained him the notice of Burke, who assisted him in various ways, and gave him an allowance of £50 a year to visit Rome. In 1770 he returned to London, and in 1771 he exhibited his first picture at the Royal Academy—the "Adam and Eve" now belonging to the Society. It was in 1777 that he began his great work, the pictures in the Society's meeting room. In 1782, after they were completed, he was appointed Professor of Painting to the Royal Academy. His career in this office was by no means happy. He seems to have been afflicted with an irritable, cross-grained temper, and this led him into disputes with everybody with whom he came in contact. He quarrelled with the artists at Rome; with everybody who criticised his pictures; with his pupils; and with many influential friends who tried to assist him. Finally, he quarrelled with the Royal Academy itself, so that he was expelled from it in 1799. He grumbled at the Society, which seems to have treated him with sufficient liberality, for it had either given him, or assisted him to procure by exhibitions, a sum amounting altogether to £700, while the members of the Society raised £1,000, and purchased an annuity of £120; but, unfortunately, only a month before his death.

He died under very miserable conditions. After his expulsion from the Academy, he seems to have supported himself mainly by the sale of his etchings from his own works. He was taken ill in an eating-house near his home, in Castle Street, Oxford Street; and, his own house being locked up, he was carried to that of a neighbour, where he died on February 22nd, 1806. Even in his death his morose nature was shown, for he locked himself in for forty-eight hours, refusing medical aid; and this, when it did come, came too late. When his works were sold at Christie's, in 1807, they fetched very fair prices, the "Adam and Eve" being purchased for 100 guineas. One of them, however, the "Pandora," which brought, though unfinished, 230 guineas, when resold in 1846, to pay the expense of warehouse room, only fetched 11½ guineas. His body was placed in the Society's Great Room for a day before it was carried to St. Paul's, to be laid beside that of Reynolds.*

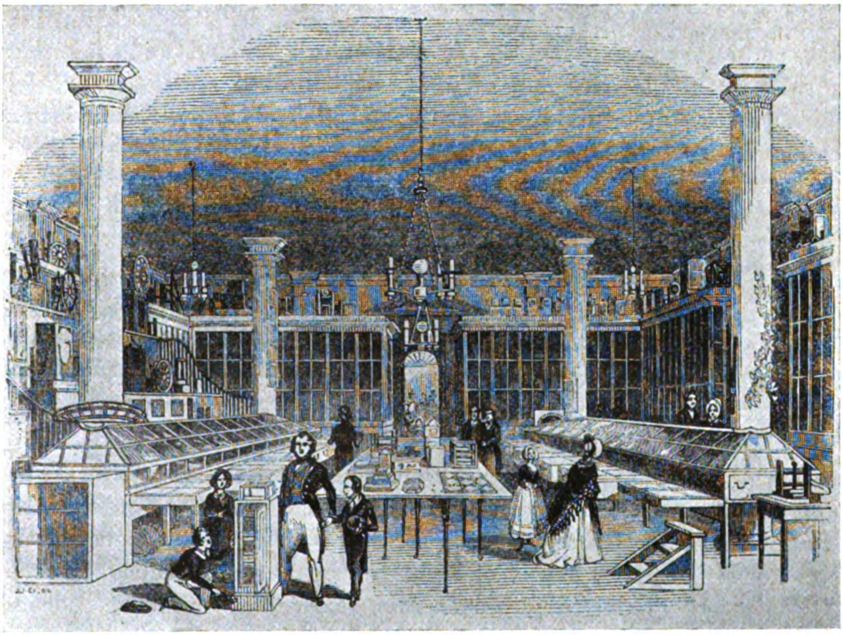
When Barry began his task he had, it is said, only sixteen shillings in his pocket, and he supported himself while it was in progress by etching. He applied to patrons, principally members of the Society, for a loan to assist him while he was at work, but it does not appear whether his applications were successful. The exact date at which the work was commenced is

* "An Account of a Series of Pictures in the Great Room of the Society of Arts . . . . By James Barry, R.A., Professor of Painting to the Royal Academy. London: Printed for the Author, by William Adlard, Printer to the Society . . . ." 1783.—*Introd.*

* Further information about Barry's life is given in S. Redgrave's "Dictionary of Artists of the English School." A longer life, written by the late S. T. Davenport, for a Dictionary of Painters, was printed in the Society's *Journal*, Vol. XVIII. p. 803. There is also a life in the "Dictionary of National Biography." In 1880, Mr. J. Comyns Carr read a paper before the Society on "The influence of Barry upon English Art." *Journal*, Vol. XXIX. p. 20.

not stated in the Society's Minutes, but the pictures were well advanced by the recess of 1778, when the key of the Great Room was entrusted to Barry, in order that he might work without interruption; and the work was continued until October, 1781. During its progress the Society's meetings were at first held in the Great Room, the pictures being covered up with canvas; but in 1781 the meetings were held in the committee room—*i.e.*, the present council room—the Great Room being given up entirely to the artist. In the same year, frames, designed by Barry himself, were procured from Mr. Adrian Maskens, of Compton Street Soho, at the expense of £100 17*s*. These frames are those in which the pictures now are, though they have, of course, been regilt since they were first put up. Not much information as to the progress of the pictures is given in the Society's Minutes. There are occasional references to the work, and payments on account of expenses incurred are authorised from time to time.

A suggestion made by the painter, that some portraits of members of the Society should be introduced gave rise to considerable discussion, and seems to have exercised the minds of the committee of "Polite Arts" for some time, but eventually a selection was made. As soon as the work was finished, a public exhibition of the pictures was held for the painter's benefit. They were shown for two months during 1783, and for the same time during 1784. The cost of these two exhibitions was defrayed by the Society, and amounted to £174. 6,441 persons attended the first exhibition, and 3,511 the second, among them being Jonas Hanway—the introducer of umbrellas—who was so pleased with the pictures that he showed his gratification by the very practical step of changing the shilling he had paid for admission for a guinea as he left. The exhibitions produced £503 12*s*. Congratulations poured in upon the artist, accompanied in some few cases at least by subscriptions or orders for paintings. But the measure of praise his pictures received was by no means equal to the artist's estimate of their deserts. In a letter, dated October 1784, to the president and members of the Society, we find him complaining bitterly of this want of taste on the part of the public. Sixteen or eighteen thousand pounds had, he says, been squandered that year at Westminster upon a "Jubilee of hackney'd German musick," "an empty hubbub of hundreds of fiddles and drums, which was dissipated in the air as soon as performed." This, too, had been attended by "well-dressed people of the first rank and condition, great Lords and Ladies with white wands, blue ribbans, and medals." Meanwhile his pictures, which were to have revolutionised English art, were being neglected in the Adelphi.



THE SOCIETY'S "REPOSITORY," A.D. 1843.

A full account of the pictures is given in

Barry's own work, above referred to. A shorter account was printed in the third volume of the Society's *Transactions* (1785), and this has been since republished in the *Journal*, with alterations, Vol. XVI. p. 604. Various other descriptions have been printed at different times, but they all seem to be derived, either directly or at second hand, from Barry's book. The whole series of pictures was intended "to illustrate this great maxim or moral truth—viz., that the obtaining happiness, as well individual as public, depends on cultivating the human faculties. To prove the truth of this doctrine, the first picture exhibits mankind in a savage state, full of imperfection, inconvenience and misery. The second represents a Harvest Home, or Thanksgiving to Ceres and Bacchus. The third, The Victors at Olympia. The fourth, Navigation, or the Triumph of the Thames. The fifth, the Distribution of Rewards by the Society. And the sixth, Elysium, or the State of Final Retribution. Three of these subjects are truly poetical, the others historical." *

The height of all the pictures is the same, 11 ft. 10 ins. The first, second, fourth, and fifth, being those at the ends of the room, are each 15 ft. 2 ins. long; the third and sixth, which occupy the north and south sides of the room, are each 42 ft. long. They all take up the upper portion of the wall, leaving a space beneath them of 10 ft. 6 ins. down to the ground.

The description of the pictures is too long for repetition, though its quaintly serious style makes it worth consultation. It may, however, be desirable to try to give a very brief explanation of the meaning of the pictures, for the use of those who care to follow out the story they are meant to tell. The first picture, the "Orpheus," is on the left-hand side of a person entering the room, and occupies the southern half of the west wall. It is intended to represent a savage people, living in a wild and desert country, while Orpheus is explaining to them the advantages of culture.

In the second picture, "A Grecian Harvest Home," we have the second, or agricultural, stage of civilisation.

The third picture, "The Victors at Olympia," which faces the visitor as he enters, is typical of the most advanced culture. At the right † of the picture, the conquerors in the games are receiving the prizes at the hands of the judges. Two of the athletes are carrying their father, Diagoras, a former victor. Near this group is another, the chief person in which is Pericles, who has borrowed the face of the Earl of Chatham. The personage in the chariot is Hiero of Syracuse; the leader of the chorus is supposed to be Pindar; the statue at the right end of the picture is Minerva; that at the other end is Hercules. The figure seated at the base of the statue of Hercules represents Barry himself

The fourth picture, "The Thames," is emblematical of the triumphs of modern commerce. The central figure represents Father Thames sitting in a triumphal car, steering with one hand, and holding in the other the mariner's compass. The car is borne along by Sir Francis Drake, Sir Walter Raleigh, Sebastian Cabot, and "the late Captain Cook, of amiable memory." In the front of the car are four figures, representing Europe, Asia, Africa, and America. Mercury, "the emblem of commerce," is represented at the top of the picture as summoning the nations, and the Nereids following the car carry several articles of the principal manufactures of Great Britain. "The sportive appearance of some of these Nereids gives a variety to the picture, and is intended to shew that an extensive commerce is sometimes found subversive of the foundation of virtue." In order to introduce the personification of music into "this scene of triumph and joy," the artist has placed amongst the sea-nymphs "his friend Dr. Burney, whose abilities in that line are universally acknowledged." "This," remarks a writer in the "Microcosm of London" (1809), was "a whim equally absurd and incomprehensible which no raillery or good counsel could induce him to dismiss from his canvas."

The fifth picture—"The Society" *—represents a distribution of the rewards in the Society. The figure near the left in nobleman's robes is Lord Romney, who was president when the picture was painted; near him is the Prince of Wales (George IV.); sitting at the corner of the picture, with a manuscript in his hand, is William Shipley, the originator of the Society; one of the farmers carrying specimens of grain is Arthur Young; the figure near him, holding a pen, is Mr. More, the then secretary. On the right of Lord Romney is the Hon. Charles Marsham, one of the Society's vice-presidents; on the left is another vice-president, Mr. Owen Salusbury Brereton. About the centre of the picture is "that distinguished example of female

* *Transactions*, Vol. III. p. 110.

† In every case *right* and *left* mean right and left of the spectator.

* The illustration is taken from Barry's etching, not from the painting, and the two vary considerably. The description in the text corresponds with the painting.

excellence, Mrs. Montague, who long honoured the Society with her name and subscription." Near her are the Duchess of Northumberland, the Duke of Northumberland, Joshua Steele, Sir George Savile, Dr. Hurd, Bishop of Worcester, Soame Jenyns, James Harris, and the two Duchesses of Rutland and Devonshire. Between these ladies "the late Dr. Samuel Johnson seems pointing out this example of Mrs. Montague to their graces' attention and imitation." Further to the left is the Duke of Richmond, and near him Edmund Burke; still nearer the right side of the picture are Edward Hooper and Keane Fitzgerald. The Duke of Northumberland, the Earl of Radnor (the second Earl), William Locke, and Dr. Hunter are examining some drawings by a youth. Near the right side of the picture are Lord Folkestone, first president of the Society, his son, the first Earl of Radnor, and Dr. Stephen Hales. The introduction of Somerset House and St. Paul's Cathedral is intended to show that the Society is in London; the picture (Barry's "Fall of Satan") and the medallion represent the arts of Painting and Sculpture.

The sixth picture represents "Elysium, or the State of Final Retribution." In it are "brought together those great and good men of all ages and nations, who have acted as the cultivators of mankind."

According to the account in the *Transactions*, the first group on the left consists of Roger Bacon, Archimedes, Descartes, and Thales; behind them stands Sir Francis Bacon, Copernicus, Galileo, and Sir Isaac Newton; near these is Columbus with a chart of his voyage; and close to him, Epaminondas with his shield, Socrates, Cato the younger, the elder Brutus, and Sir Thomas More. Behind Brutus is William Molyneux, holding "his book of the Case of Ireland"; near Columbus are Lord Shaftesbury, John Locke, Zeno, Aristotle, and Plato; and in the opening between this group and the next are Dr. William Harvey, the discoverer of the circulation of the blood, and Robert Boyle. King Alfred is leaning on the shoulder of William Penn, who is showing his code of laws to Lycurgus; standing round them are Minos, Trajan, Antoninus, Peter the Great of Russia, Edward the Black Prince, Henry the Fourth of France, and Andrea Doria of Genoa. Then come patrons of genius, Lorenzo de Medici, Louis the Fourteenth, Alexander the Great, Charles the First, Colbert, Leo the Tenth, Francis the First, the Earl of Arundel, and "the illustrious Monk Cassiodorus"; behind the archangel are Pascal and Bishop Butler, behind whom again is Bossuet, his hand resting on the shoulder of Origen. Behind Francis the First and Lord Arundel are Hugo Grotius, Father Paul, and Pope Adrian.

"Near the centre, towards the top of the picture, sits Homer, on his right hand Milton, next him Shakespeare, Spenser, Chaucer, and Sappho; behind her sits Alcæus, who is talking with Ossian; near him are Menander, Molière, Congreve, Bruma, Confucius, Mango Capac, &c. Next Homer, on the other side, is the Arch Bishop of Cambray, with Virgil leaning on his shoulder; and near them Tasso, Ariosto, and Dante. Behind Dante, Petrarch, Laura, Giovanni, and Boccaccio. In the second range of figures, over Edward the Black Prince and Peter the Great, are Swift, Erasmus, and Cervantes; near them Pope, Dryden, Addison, and Richardson. Behind Dryden and Pope are Sterne, Gray, Goldsmith, Thompson, and Fielding; and near Richardson, Inigo Jones, Sir Christopher Wren, and Vandyke. Next Vandyke is Rubens, with his hand on the shoulder of Le Sueur; behind him is Le Brun; next are Giulio Romano, Dominichino, and Annibale Carracci, who are in conversation with Phidias, behind whom is Giles Hussey. Nicolas Poussin and the Sicyonian maid are near them, with Callimachus and Pamphilus; near Apelles is Correggio; behind Raphael stand Michael Angelo, and Leonardo da Vinci; and behind them Ghiberti, Donatello, Masaccio, Brunaleschi, Albert Durer, Giotto, Cimabue, and Hogarth. In the other corner of the picture the artist has represented Tartarus, where, among cataracts of fire and clouds of smoke, two large hands are seen; one of them holding a fire-fork, the other pulling down a number of figures bound together by serpents, representing War, Gluttony, Extravagance, Detraction, Parsimony, and Ambition; and floating down the fiery gulph, are Tyranny, Hypocrisy, and Cruelty, with their proper attributes."*

It is stated in the *Transactions*, Vol. XXIII. p. 18, that on the death of Lord Nelson in 1805 "the Society proposed to commemorate that hero by introducing his portrait in one of the pictures which decorate the Great Room," and Barry undertook to execute the work, but his death prevented the design from being carried into execution.

The six pictures did not occupy the whole wall of the room, the spaces over the chimney-pieces at either end being filled by the portraits of Lords Romney and Folkestone, before referred to. It does not appear that Barry's original design included pictures for these spaces, but we find him, in 1801, expressing a wish that these two portraits should be placed in

* *Transactions*, Vol. III. p. 128.

some other room of the Society, and that he should be allowed to execute pictures which might fill the vacant spaces. This he was willing to do without charge, and without interruption to the business of the Society. The cost of them would not, he said, exceed £10 for canvas and stretchers. It may be supposed, and indeed it appears from the style of the letter, that he was, at that time, perfectly well satisfied with the treatment he had received from the Society, for he expresses himself as being "both gratified and flattered with the publick reputation of the pictures." Permission was given to Barry to carry out his scheme, and it may be presumed that it was upon the receipt of such permission that he prepared the two designs which are still preserved amongst his etchings, representing George the Third and Queen Caroline. But, although the proposal was at first readily accepted, it seems to have given rise to some difference of opinion, for the then president, the Duke of Norfolk, notified his intention of moving to rescind the resolution of the Society for the removal of the portraits. Under these circumstances, Barry at once withdrew his offer, at the same time disclaiming any intention to show disrespect to the memory of the first two presidents of the Society. He urges very fairly that another position might be found for the pictures, which would be in no way injured, and that his design could then be harmoniously completed. Coming from a man of his temper, it must be allowed that his second letter is most dignified, and in excellent taste. The portraits consequently remained in their places until 1864, when they were removed to make way for the portraits of the Prince Consort and the Queen, by J. C. Horsley, R.A., and W. C. Cope, R.A. These, with the bust of Prince Albert now standing in the ante-room, form the memorial which was provided in 1863 by subscriptions from members of the Society in memory of their president.

It is needless to say that these celebrated pictures have always been an object of great care to the Society. Looking through the Minutes since the commencement of the century, we find constant references to the attention bestowed upon them. In one place, instructions are given to the housekeeper that they should be carefully wiped down every year; in another we find West, and later on Mulready, reporting on their condition. The frames were regilt several times, and so on. The pictures have been cleaned at various times; about 1834 it is said that a thick coat of olive oil, which had been applied to them under some mistaken notion of preserving them, was removed. In 1846, when the room was redecorated by Hay, of Edinburgh, the way in which the pictures had been treated called forth a good deal of adverse criticism, and it was then that Mulready was called in to report upon them. His report was that they were in excellent condition, and that nothing appeared to have been done to them which had inflicted the slightest injury. This opinion was confirmed by the opinion of Seguier, the picture restorer. "The Orpheus" had, either then or at some previous time, been badly varnished, and stains from this treatment are still perceptible. In 1863 they were relined and stretched upon new frames by Merritt, a well-known picture cleaner, at a cost of £220. In 1880 they had got to be extremely dirty, and they again underwent a thorough cleaning. Since that date they have been cleaned every year.

Besides the pictures in the Great Room, the Society possesses the plates of a number of etchings by Barry, most of which were presented to the Society in 1851 by Miss Barnett. Some of these may have been done while he was at work upon the pictures, but most of them probably during his later years. Six of them represent the six pictures. They were etched after the completion of the pictures, and were copied from the originals by the artist himself, yet, curiously enough, they differ in many of the details from the paintings. It is true that some slight alterations were made by Barry in the pictures after they were first painted, but this does not seem sufficient to account for all the variations. The other etchings are nearly all from pictures of the artist, most of which are no longer extant. The Society also possesses Barry's "Adam and Eve," one of his more important works, which, as above mentioned, was sold after Barry's death at Christie's. It was presented to them by Mr. R. H. Solly. This picture has been for some years on loan at the Victoria and Albert Museum. There is also a portrait of Barry, painted by himself, which is hung up in the ante-room, and an oil painting which is said, it is not known on what authority, to be a portrait by him of his mother. The former was presented to the Society by Mr. W. Moffat. There seems to be no record in the Society's Minutes of the way in which the latter picture came into the Society's possession, and there is much doubt as to its authenticity.

Besides the pictures above mentioned, the Society possesses the following portraits:—

Full-length painting of Jacob, Viscount

Folkestone, first president of the Society of Arts, by Thomas Gainsborough, R.A. This picture was painted by Gainsborough in 1776. It was a copy of a three-quarter portrait by Hudson (1749); enlarged to full length by Gainsborough to match the portrait of Lord Romney. The fee paid to the artist was a hundred guineas. Dance had previously been asked to do the work, and had undertaken to do so, but eventually was unable to carry out the commission.

Full-length painting of Robert, Lord Romney, second president of the Society of Arts, by Sir Joshua Reynolds, P.R.A. This portrait was painted for the Society in 1770. The price paid to Sir Joshua Reynolds was 150 guineas.

Portrait of William Shipley, "whose public spirit gave rise to this Society." Painted by Richard Cosway, R.A., and presented by him to the Society in 1785, through the intervention of Caleb Whitefoord, V.P.

Portrait of Peter Templeman, M.D., secretary of the Society from 1760 to 1769. Painted by R. Cosway, R.A., and presented by Caleb Whitefoord, V.P.

Portrait of Samuel More, secretary of the Society from 1769 to 1799, by Benjamin West, P.R.A. This was painted for the Society in 1796. The amount paid the artist was £66 8s.

Portrait of Sir Frederick Bramwell, Bart., president of the Society in 1901. Painted after Sir F. Bramwell's death by Seymour Lucas, R.A., and presented to the Society by H. Graham Harris, V.P., in 1904.

Portrait of Sir Henry Trueman Wood, secretary of the Society from 1879. Painted by Sir Hubert von Herkomer, R.A., and presented by the members of the Council in 1902.

Portrait of Dr. Frederick Crace Calvert, F.R.S. Presented by Mrs. Calvert (1876). He delivered several courses of Cantor lectures—the first in 1864.

Portrait of Miss Ann Birch Cockings, housekeeper and registrar of the Society (1802–1844). Painted and presented to the Society by Miss E. A. Drummond (1882). Miss Cockings was a personage in her time, and apparently a lady of some humour. She is said to have retorted to an importunate applicant who wanted to interview the secretary, that "one old woman ought to do as well as another."

The bust of the Prince Consort has already been mentioned. This was the work of William Theed, a sculptor of some repute in the last half of the nineteenth century. He was employed to produce statues and busts of numerous eminent persons, and his work is to be found in Westminster Abbey, at Windsor, in the London Guildhall, and also in Calcutta, Manchester, Liverpool, and elsewhere. His best-known work is the colossal group representing Africa, at the north-east angle of the Albert Memorial. He was born in 1804, and died in 1891.

The statue at the foot of the staircase is of Joshua Ward, a well-known character in his time (1685–1761). Ward, known as "Spot" Ward from a mark on his face, was a quack doctor, who amassed a large fortune by the sale of his remedies. In his later life he was very popular, and had many patrons, including George II. In 1740 he introduced into England an improved method of manufacturing sulphuric acid, already practised on the Continent, and set up works for the purpose at Twickenham and Richmond. The process was afterwards perfected by Roebuck. The statue is by Agostino Carlini, and was presented to the Society in 1792 by Ralph Ward, Ward's grandnephew, and one of his heirs.

The Society also possesses a bronze bust of Sir George Birdwood by Alfred Gilbert, R.A., a replica of one presented in 1900 to the University of Bombay by some Indian friends of Sir George, and a terra-cotta bust of Sir Edwin Chadwick, the well-known sanitary reformer (1800–1890), by George Tinworth. It was presented to the Society by his daughter in 1905.

THE ANCIENT FRESCOES AT CHICHEN ITZA.*

The ruins of Chichen Itza in Yucatan are amongst the most important in Central America, being especially remarkable for the number of coloured portrait sculptures and frescoed walls. The frescoes have been sadly destroyed in the course of centuries, but enough remain to provide striking pictures of the life of the ancient folk. In two of the upper rooms of the building called the Nuns' Palace, the walls and vaulted ceiling were entirely covered with scenes which had backgrounds with thatched houses and trees, also temples with high-pitched roofs enclosed within battlemented walls. There were groups of warriors armed with spears, *atlatls* (throwing sticks), and round shields, and others seated on the ground, with ornamental tails hanging from their girdles. The drawing was firm and spirited, the colouring vivid and harmonious.

Stephens observed a row of Maya glyphs painted just below the vaulting in the interior of the small building known as the Iglesia, but they have disappeared, and there are no signs of any glyphs

* Abstract of a paper read by Miss A. C. Breton before the Anthropological Section of the British Association at Portsmouth, 1911.

among the paintings at Chichen Itza. The chambers of the Akaboib have been whitewashed in modern times, and only a blue band along the edge of the vault is now visible. In the narrow corridor of the Caracol, too, very little colour is left.

The building at the south end of the eastern wall of the great Ball Court, usually called Temple of the Tigers, contains in its upper part the best preserved paintings yet discovered. The outer chamber having been filled with débris owing to the fall of the roof when the wooden lintels gave way, the inner chamber also became partly blocked and difficult of access, until Dr. Le Plongeon in 1884 cleared away most of the accumulated material, and partly copied the paintings in it. Visitors wrote their names over the frescoes, bats lived at one end, swallows at the other, and bees made tunnels in the plaster. Still it has been possible to secure many of the details, and to give some idea of the composition. The chamber is about 26 feet long, and not quite 8 feet wide, and 22 feet high to the top of the vault, with the door in the middle of the long western side. Each of the long sides is divided into three panels, of which the four end ones represent landscapes full of armed warriors, as do those of the north and south sides, with houses above, and tents and temporary buildings below, where chiefs are consulting and priests perform rites of divination. These panels are divided by a blue band from a dado with mythological figures and plants.

The south-west end is the most complete, and has about 120 figures, almost all of them placed at certain distances and angles from each other. These distances were measured from the point where the nose of each figure appears above the shield, and form the basis of the composition. The position of the shields fixed, the artist then drew the figures according to his fancy, and no two are alike. In this scene the attacking party are distinguished from the defenders of the village above by a difference in costume. The former have cotton knee and ankle bands, small green shields at their backs with hanging streamers, and round green earrings and necklaces. Their head-dresses, surmounted by long feathers, are more elaborate than those of the villagers. The latter have a round, stiff headpiece with two or three blue feathers standing up from it, oblong ear ornaments which pass through the elongated lobes, white shirts and round shields, usually with a crescent in the centre as device. All cast their spears from *atlatls*. The chiefs, who sit in consultation below, have feather mantles like those of the portrait statues which supported the sculptured table in the outer chamber.

The narrow south end panel also has a scene of attack, with high scaffold towers and a ladder of a notched tree-trunk, on which some of the assailants are perched. Here the men are taller and more athletic than in the previous scene. In the following panel there are more important houses, forming a town, with a forest on both sides, in which are animals, snakes and birds. Beyond come the Red Hills on which wilder figures are grouped, with rocks and trees below. The north end is much destroyed, but some personages on a background of blue sky may represent departed heroes. The shields in this are oblong. The last of these scenes shows a group of houses inside a defensive barrier, and blue warriors in feather cloaks have conquered the inhabitants. Above the door a life-size recumbent figure may be the hero in whose honour the building was erected.

INDIA WITH RESPECT TO THE WORLD'S COTTON SUPPLY.*

Shortage of raw cotton has become an almost chronic condition with which the cotton manufacturer has to contend. It has produced abnormally inflated prices, given an opportunity to cotton gamblers, caused loss and embarrassment to manufacturers, and produced distress among cotton operatives. "Shortage" has not been produced by a falling-off of the world's output of raw fibre, nor by an increased demand by Lancashire for cotton, but by an enormous growth in the manufacture of cotton goods on the Continent of Europe and in the United States of America. In eighteen years prior to 1910 Britain's demand for raw cotton has fallen 4 per cent., while during the same period Europe's requirements have increased 70 per cent., and this on a figure much larger than ours. America, during the same time, has increased her demand 90 per cent., and her total consumption of fibre now exceeds that of Britain by no less than 54 per cent. Thirty years ago the total American crop of cotton was less than seven million bales, but, supplemented by the small crops of other countries, was sufficient to supply the world's demands and leave a surplus each season, keeping the price reasonable and fairly regular. Now, with an American crop nearly double the figure just quoted, and with increased supplies from other fields, and with the demand of Lancashire stationary, the price of raw fibre has doubled, and "shortage" has become rampant, notwithstanding the restricted time worked in the mills. The difficulty apparently gets worse month by month, and unless measures of amelioration are successfully pressed, the cotton industry of Lancashire must decline, and ultimately be starved out of existence. India at present produces almost half the weight of cotton grown in the American fields, and has, roughly, 20,000,000 acres under cotton crops. Indian fibre is, however, of short staple and, therefore, very little used in Lancashire. Britain consumed only 87,592 bales during the year ending August 31st, 1910. Many experts believe that with properly directed effort the crop of Indian cotton may be doubled in the course of a few years. If this can be done, even if the staple

* Abstract of a paper read by Mr. J. Howard Reed, F.R.G.S., before the Section of Economic Science and Statistics of the British Association at Portsmouth, 1911.

is not improved, it will take the place of much long-fibred cotton now used throughout the world, and set free for Lancashire a proportionate amount of better material. The cultivation of cotton in India is very primitive. The lands are poorly tilled, inadequately manured, and meagrely watered; while the native farmer is not only very unprogressive, but is harried by unscrupulous money-lenders, crippled by poor seed, and handicapped by insect pests. With selected seed, longer-stapled cotton can be grown, but the native ryot finds it gives a lighter crop, and as he can under present conditions only obtain the same price as for the shorter-stapled cotton, he naturally soon reverts to the cultivation of short-stapled fibre. This is largely an economic difficulty, which can be met by the establishment of recognised buying and ginning centres, and the founding of co-operative credit banks, each under scientific and official control. The Agricultural Department of India has done much to improve matters, but larger grants are required to enable it to do more. There is enormous scope for its usefulness. The native people need to be taught better methods of farming, modern agricultural machinery should be introduced, proper rotation of crops insisted upon, ample manuring provided for, better seed made available, honest methods of financing established, and well-placed and easily accessible ginning and buying centres set up. If work of this kind is taken in hand in a thoroughly efficient manner, more acres can be brought under cultivation, and the number of cotton cultivators will multiply. The development of railways, roads, and irrigation works, already in a highly organised condition, will advance as the demand for them grows. India has in the past produced better cotton, and can do so again under properly regulated conditions. Any efforts which can bring this about are well worth making, as their success means vast advantage to the agriculturists of India, a relief from the present serious strain in the cotton world, and the salvation of the great industry of Lancashire.

AGRICULTURAL RESEARCH.

As the result of communications between the Board of Agriculture and Fisheries and the Development Commissioners, the Treasury have now sanctioned the allocation of funds—which, when the scheme is in full operation, will amount to £50,000 per annum—to be distributed by the Board for the purpose of promoting agricultural research.

The scheme provides for:—

1. A system of agricultural research which will secure for each group of the problems affecting rural industry a share of attention roughly proportional to its economic importance.

2. The concentration of the scientific work on each group at one institution or at institutions working in combination.

3. Grants for special investigations for which provision may not otherwise be made.

4. The grant of scholarships with a view to the increase of the number of men fully qualified to undertake agricultural research.

5. The carrying out of investigations into problems of local importance, especially those involving the application of modern research to local practice, and the provision of scientific advice for farmers on important technical questions.

In making arrangements for the separate investigation, as far as possible, of each group of allied subjects the Commissioners and the Board have been impressed with the importance of securing continuity in work which is necessarily of considerable duration, and at the same time of providing staffs of specialists and experts who will be permanently engaged on work arising from the investigation of the same group of problems. By this means concentration and economy of effort will be better secured than it would be if a number of institutions were dealing at the same time with the same group of problems.

It has been arranged that grants should be made for research in the following groups of subjects:—

1. Plant physiology.
2. Plant pathology and mycology.
3. Plant breeding.
4. Fruit growing, including the practical treatment of plant diseases.
5. Plant nutrition and soil problems.
6. Animal nutrition.
7. Animal breeding.
8. Animal pathology.
9. Dairying.
10. Agricultural zoology.
11. Economics of agriculture.

A sum not exceeding £3,000 per annum will be available for assistance in respect of special investigations for which provision is not otherwise made.

Grants from this fund will be made on the recommendation of the Board's Advisory Committee on Agricultural Science, who will consider not only whether the proposed investigation is desirable in itself, but whether it could not be better carried out at one of the special research institutions referred to above. The grants will be made from year to year, and will be for one year only in each case.

In order to secure the services of a number of carefully trained men for work in connection with the scheme, the Board propose in each of the years 1911, 1912, and 1913, to offer twelve scholarships, of the value of £150 per annum, tenable for three years. It is proposed that candidates for scholarships should be selected by a special committee representing the institutions under whom the selected candidates will subsequently work. The award of twelve scholarships will be conditional on a sufficient number of thoroughly suitable candidates presenting themselves.

Grants will also be made to certain universities, university colleges, and agricultural colleges in

England and Wales for the purpose of enabling them to supply scientific advice to farmers on important technical questions and to carry out investigations into problems of local interest, which can be more conveniently studied on the spot than at one of the research institutions.

By means of these grants it is hoped to provide an expert staff possessing both scientific and practical qualifications, who will devote themselves to solving difficult local problems and in other ways endeavour to secure the application of science to practice.

THE CATTLE-BREEDING INDUSTRY OF ARGENTINA.

Argentina ranks third in the world as a cattle-producing country. Russia and the United States alone lead it, but Argentina has only about six million inhabitants to feed, which accounts for the fact that it is the leading country in beef exports. Russia and the United States must consume most of what they produce. Argentina ships the greater proportion of what it produces ; not only oxen, but horses, sheep, wool, maize, wheat and flax-seed. At the last census, taken about two years ago, there were twenty-nine million cattle in Argentina and about six millions in Uruguay. This is, according to the International Bureau of the American Republics, nearly all stock of the best English blood—Shorthorn, Hereford, and Aberdeen Angus. Argentina and Uruguay cattle are reared under conditions somewhat peculiar to the locality. They are not range cattle, nor yet exactly farm cattle, and are given but little grain, yet the export steers of Buenos Aires or Montevideo are fully equal in size, and will cut as much prime beef and as little waste as the best steers of Kansas, Pennsylvania, or south-west Virginia in the United States. The word "estancia," which primarily connotes the central habitation, has come to include in the Argentine Republic the whole farm plantation, or ranch. The "estancias" are of all sizes, from the small farm of a few hundred acres to the large plantation of 30,000 or 40,000 acres. Only a few "estancias" are cattle or sheep ranches alone; they are grain farms as well. The cattle are fattened on cultivated grasses in permanent pastures. Alfalfa is the principal grass. When once properly set, alfalfa requires no replanting for ten years or more. As a general rule, cattle, up to the time of finishing for market, are given free range on the native grasses, or *pasto fuerte*. It has been estimated that the native grass in the outlying provinces will carry one ox to every six acres, or one sheep to the acre. In these distant pampas, the grass is not so good and water is scarce. Most of the cattle are brought down to the rich alfalfa pasturage nearer market, to be fattened. Land which will carry eight hundred animals to the league, or one to eight acres, when put into alfalfa will easily carry three thousand to the league. In the central provinces of Buenos Aires,Cordoba, Santa Fé, Entre Rios and Corrientes, the native grasses are better, and more alfalfa is grown. These five are the principal cattle-producing provinces, as they are also the principal grain-producers. Next to these come La Pampa, Santiago, and Salta, each of which has from seven hundred thousand to one million cattle. Then come San Luis, Mendoza, La Rioja, and Catamarca, averaging about half these numbers. In the north, Missiones, Formosa, and El Chaco, and in the south Rio Negro and Chubut, are rapidly becoming important cattle districts. Even San Juan and Neuquen, on the Andean slope, and Santa Cruz and Tierra del Fuego in the extreme south, are finding that cattle, as well as sheep, can be bred with profit. In fact, there is but little territory in the Argentine Republic which is not suitable for either cattle or sheep. Beef is exported from the La Plata region—salted or as meat extracts, and frozen in quarters. England is the principal market for South American beef. The frozen meat industry in the Argentine Republic has grown considerably during the last few years. In the year 1908 the Argentine Republic exported 60,916 head of cattle, three-fourths of which went to Chile. It exported 2,295,784 quarters of frozen beef, and from the salting works 155,400 beeves as salt beef, meat extract or jerked beef. In this latter industry, Uruguay exported 754,300, and southern Brazil 425,000 head respectively.

HOME INDUSTRIES.

Improving the Loom.—The *Manchester Guardian* describes a novel device for arresting the flight of the shuttle on a cotton loom—the joint invention of several Blackburn cotton men—that has just been patented. Instead of being hinged in the shuttle-box, the "swell," which is of the usual type, is allowed some freedom of movement in the direction of travel of the shuttle. A wedge at the back of the "swell" is held in position laterally by a spring, so that when the "swell" is carried along by the friction and motion of the shuttle, a gradually increasing hold is produced, and the shuttle is brought to rest without damage to the picker, the life of which, it is claimed, is thus very considerably increased. The operation of this device upon the shuttle renders it possible to dispense largely with checking and bumping straps, and it is claimed that the "travel" of the shuttle is so much improved that a better twist and weft weave is obtained. After an extended trial, the invention is now in regular use in about a dozen of the principal weaving sheds at Blackburn.

The Electrical Industry.—The electrical industry of the country cannot be said to be in a satisfactory condition, and there are many explanations of it. Among other things, it is complained that there

is no association which adequately represents the interests of the British electrical manufacturers as so many other industries are represented; an association to promote the consideration and discussion of questions affecting the electrical manufacturing trade, and generally to watch over, protect, and promote the interests of persons engaged in electrical manufacturing. The National Electrical Manufacturers' Association was founded some eight years ago to do all this, but hitherto, for one reason and another, it has not done all that was expected of it. It has failed to include in its membership many large and influential firms, and though it has done much useful work with the means at its disposal it has been crippled from the lack of adequate funds. It is now to be reorganised, and in future it will be known as the British Electrical Manufacturers' and Allied Trades' Association. The basis of subscriptions has been rearranged, it is expected that the revenue will be largely increased, it has appointed Mr. D. N. Dunlop, the sales manager of the British Westinghouse Electric and Manufacturing Company, as its secretary, and it will have its representatives in all parts of the world, sending information and assisting the British electrical manufacturer in ways that should lead to a much larger output of electrical apparatus in England. The programme of the reorganised association is said to have received the support of the leading electrical firms who have hitherto held aloof, and it may be hoped that this will tend to the good feeling towards each other which is so eminently desirable, but which has not always been existent, in the relations of electrical manufacturers towards each other.

The Coal Mines Bill.—It may be hoped that when this Bill is further considered by Parliament the clause which bars the internal-combustion locomotive from being introduced into collieries will be reconsidered. On the face of it, it seems undesirable to reject such a means of transport. These machines are largely used in continental and colonial collieries for underground haulage. They have been in use since 1903; their employment is becoming more general; they offer considerable economy to all mines, more especially to certain small mines which have been most affected by recent legislation; and the use of these machines is officially sanctioned by the German, Austrian, Belgian, and Dutch authorities. In the colonies, too, these machines are sanctioned and are at work. The Government appear to object to their introduction in British mines, fearing accidents, but if they can be used safely in foreign mines it is difficult to understand why they should be barred in this country, not merely in certain mines but in all. No doubt there would have to be stringent regulations governing their usage, as abroad, but it has not been demonstrated that the regulations cannot be enforced.

The Mining Industry.—The unrest in the mining industry continues, and in parts of Wales it has taken almost a revolutionary character. The Miners' Federation of Great Britain is opposed to a national strike on Welsh behalf, and some of their own leaders have advised the Welshmen to submit to the will of the Federation, but the men in certain districts seem to be quite out of hand. The treasurer of the South Wales Miners' Federation, supposed to be a moderate man, predicts a national strike for the minimum wage, but meanwhile the Coal Mining Association of Great Britain has agreed to meet the Miners' Federation of Great Britain to discuss the minimum wage question. The difficulty is to define an abnormal place, and to fix a general minimum. It is to be hoped that some solution of the problem will be found, and that anything like a national strike of miners will be avoided. Few probably realise the enormous injury that would be inflicted upon numerous home industries by the stoppage of normal coal supplies, even for a few days, and the small stocks of coal held by manufacturers and others controlling these industries.

Hop Drying.—The Germans have invented many hop-drying apparatus, but those that are satisfactory in other directions are usually barred upon the score of expense. A large capital expenditure for the drying of hops is not justified, but the need for some better system than that which is still general is apparent. Kentish growers are feeling the competition of German and American hops, which are often of superior quality to the English as a consequence of the better methods of drying in vogue in those countries. The criteria of well-dried hops are thus described by a writer in the *Times*:—To meet the brewers' requirements dried hops should contain about 10 per cent. of moisture. Apart from the fraud of selling them in too moist a condition, it is of great importance that they should not contain more than this amount, and that the contents of the packages, or "pockets," should be evenly dried throughout, else damage will be caused by mould-growths and changes which lead to heating. If the hops are too dry they will not stand handling well, and large losses of the valuable hop-resins have been traced to the friability of the dried hop cones, the leaves of which hold and protect the seeds around which the resins lie. The colour of the hops and their quality for brewing depend upon the heat treatment, the temperature employed, and the duration of the heating. The favoured colour appears to be green with a light amber shade. Too high a temperature, or too long an exposure, will give hops a poor colour and is apt to cause deterioration in the quality of the resin and to lessen its quantity.

Yeast.—Foreign competition continues to tell upon the yeast industry. For many years it has been a very profitable "side line" of the grain-spirit distillers and vinegar makers. At one time foreign competition was negligible, but of late Belgium, Germany, Holland, France and Denmark have become serious competitors, and about one-third of the yeast supplies comes from those

countries. The British output of yeast is approximately 16,000 baskets, of 56 lbs. each, a week, some 8,500 baskets being imported. The Belgian and Dutch yeast is of a low grade. The British output steadily increased until 1905, when foreign competition first became serious. The foreign maker is in a strong position, since he has a protected home market for spirits and is not trammelled by revenue restrictions. The British producer complains that he is precluded from separating more than 15 per cent. of yeast from his mash in a brewing period, although he can easily separate 20 per cent. without seriously reducing the output of spirit.

Railway Charges.—If in consequence of a readjustment of wages Parliament is to be asked to sanction increased freight charges, there is something to be said for the suggestion that it would be better to raise the passenger fares in certain directions. An increase of freight charges might seriously hamper trade, but passengers might well pay a little more for the services they enjoy. The great improvements in the railway service of recent years have benefited neither the companies nor the employees, the benefit has gone to the passengers. They have much more luxurious travelling at much cheaper rates than formerly, at rates that are really too low. It is with some of the railway services as with the omnibus companies. The public are given too much for their money. Assuming that, as a result of the recommendations of the Commission now sitting, the railway companies have to pay their employees higher wages, it might be better if they put up passenger rates to some extent, and on certain services, rather than add to freight charges, which as they stand greatly handicap home traders in competing with the foreigner—much more favourably placed. The only railway freight rates which railway companies can increase without immediate danger of losing revenue are those on traffic absolutely dependent on the railway service, and this is already paying rates relatively higher than traffic which can get to its destination by alternative means of transport. The charges on mineral traffic may seem to admit of some increase, for it is still carried at very low rates, but the principal mineral commodity is coal, and coal rates were recently increased. Besides, coal is an important item in railway expenditure, and further increase in railway rates might lead to retaliation from the colliery proprietors, which might mean greater loss to the railway companies than the gain that would accrue to them from increased freight rates. Sea competition and inland navigation are facts which even an act of Parliament cannot nullify.

OBITUARY.

H.H. The Maharaja of Cooch Behar, G.C.I.E., C.B.—Colonel His Highness Sir Nripendra Narayan Bhup Bahadur, Maharaja of Cooch Behar, died on the 18th inst. at Bexhill. His Highness came to England for the Coronation, but illness prevented the carrying out of his intention to return to India at the end of the present month. The Maharaja was elected a member of the Society in 1901, and his loss is to be regretted as that of an eminent representative of the ruling chiefs of India. He bore a high reputation as an administrator, a reformer, and a sportsman, and was extremely popular both in his native country and in England. His character and services were fully appreciated by the three Sovereigns under whose reigns he lived. He was made a G.C.I.E. and a C.B. by Queen Victoria, and was an Honorary A.D.C. both to King Edward and to King George.

The Maharaja was born in 1862, and, as his father died before he was a year old, he had a very long minority, during which his territories were administered by the Government. Since his coming of age, he introduced many reforms and improvements in the State under his government, and he also served in the North-West Frontier Campaigns of 1897. He was a frequent visitor to England, and had many friends in this country.

GENERAL NOTES.

Whisky Age Certificates.—Since January 1st, 1908, Australian producers have had to bond their spirits for the statutory period of two years, the Spirits Act of 1906 having come into force at that date. They have now induced the Commonwealth Government to enact that, as from January 1st next, all imported spirits (other than gin, Genevan hollands, schnapps, and liqueurs) shall have been stored in wood for not less than two years, and they must be accompanied by an official Excise certificate to the effect that they have been so stored. In the absence of this certificate storage in Australia will be necessary. Nearly all the whisky shipped to Australia is more than two years old, but the Scotch Whisky Exporters' Association, and other trade bodies, are making strong representations to the Government, being fearful that owing to the shortness of the interval before the new regulation comes into force their interests will be seriously prejudiced. Australia is one of the principal export markets for Scotch whisky, so that the matter is one of importance to the trade.

Highest Electric Line in Italy.—The highest altitude yet reached by any line worked by electricity in Italy is that of the tramway from Biella to Oropa, the culminating point of which is 1,150 metres (3,735 feet) above the sea level. Oropa, which is situated among the mountains to the north-west of Biella, is much frequented during the summer on account of its pilgrimage church and hydropathic establishment. The line is about 14 kilometres (nearly nine miles) in length, and can carry upwards of 2,000 passengers per day.

THE MANUFACTURE OF BRANDY IN GERMANY.—The *Deutsche Wein Zeitung*, in a recent article entitled "Die deutsche Cognacindustrie," appears to ignore the fact that "Cognac" being the name of a French town, any brandy with that title made in Germany cannot be the genuine article. It gives some interesting statistics relating to the manufacture of brandy in that country. During the financial year 1908-9 the total number of brandy distilleries throughout the empire were 173, producing 11,348 hectolitres (249,546 gallons) of that spirit. In 1909-10 the number of factories and amount of production were as follows:—

	Distilleries.	Hectolitres.	Gallons.
Prussia	106	7,944	174,768
Bavaria	24	3,661	80,542
Hesse	16	854	18,788
Baden	10	342	7,524
Other Provinces	13	813	17,886
	169	13,614	299,508

The quantity of raw material (wine, etc.) dealt with in these establishments annually since 1900 was the following:—

Financial Year.	Hectolitres.	Gallons.
1900-1	38,655	850,410
1901-2	38,829	854,238
1902-3	24,286	534,292
1903-4	20,996	461,912
1904-5	32,990	725,780
1905-6	27,564	606,408
1906-7	30,963	681,186
1907-8	29,453	647,966
1908-9	63,366	1,394,052
1909-10	71,417	1,571,174

From this it will be seen that the immediate effect of increasing the duty on French cognac in 1909, from 160 marks to 225 marks per hectolitre (7*s*. 3*d*. to 10*s*. 3*d*. per gallon), was nearly to double the production of brandy in Germany. On the other hand, the increase of duty caused a loss to the revenue of upwards of 4,800,000 marks (£240,000).

SNAKES AND WILD ANIMALS IN INDIA.—The number of lives lost in India from snake bites, instead of diminishing, shows a lamentable tendency to rise. According to a statement published by the Home Department of the Government of India, the total of deaths from this cause in 1910 was 22,478, an increase of 1,114 over the figure for 1909, and of 2,740 over that of 1908. The increase in Eastern Bengal and Assam is attributed to snakes being driven by high floods to take refuge in the raised village sites. Both in this province and in the United Provinces a considerable number of cases were treated with the Brunton lancet and permanganate of potash, and a high proportion of them are reported to have recovered. No reliable deduction can, however, be drawn from the use of this lancet, owing to the lack of proof that the bites it was used upon were really those of poisonous snakes. The number of persons killed by wild animals last year was 2,400, compared with 2,496 in 1909; 55 were killed by elephants, 853 by tigers, 351 by leopards, 109 by bears, 319 by wolves, 25 by hyaenas, and 688 by "other animals." Some idea of the damage done by wild animals may be gathered from the fact that no fewer than 93,074 cattle were destroyed by them in 1910. The figures upon the other side of the account are also striking. The number of wild animals killed in 1910 was as follows: elephants, 23; tigers, 1,421; leopards, 5,029; bears, 2,292; wolves, 3,114; hyaenas, 414; other animals, 6,989; snakes, 91,104.

SYNTHETIC RUBBER.—A patent for manufacturing a substitute for indiarubber from the Soya bean has lately been taken out in Germany. The process consists in reducing the oil of this bean to the consistency of a thick paste by treating it with nitric acid. The paste, after repeated washings in some alkaline solution, is then heated to a temperature of 150° C. (402° F.). The product thus obtained is said to be quite homogeneous and elastic, and resembles indiarubber. It can also be vulcanized.

NUMBER OF NEWSPAPERS AND PERIODICALS IN FRANCE.—In 1640 only one newspaper was published in France, and it was not until 140 years later, namely in 1780, that the number was increased to twenty-four. In 1790, a time of political unrest, no fewer than 350 were published; in 1826, 490; and in 1874, 2,024. At the present time the total number of newspapers published exceeds 8,000. With respect to periodicals, France at the present time, heads the list with 8,940; Germany, 8,050; England, 4,329; Italy, 3,068; Belgium, 2,029; Russia, 1,661; Holland, 1,402; Spain, 1,350; and Switzerland, 1,322.

POPULATION OF GERMAN CITIES. — Advance figures compiled from the 1910 Census returns show that there are now in the German Empire forty-seven cities of more than 100,000 inhabitants. Of these seven have more than 500,000. They are Berlin (without suburbs), 2,064,153; Hamburg, 936,000; Munich, 593,053; Leipzig, 585,743; Dresden, 546,882; Cologne, 511,042; and Breslau, 510,929. Four others have more than 300,000 inhabitants. They are Frankfort-on-the-Main, 414,406; Düsseldorf, 356,733; Nuremberg, 332,539; and Charlottenburg (a suburb of Berlin), 304,280. Twelve other cities have over 200,000 inhabitants, and twenty-four others have populations ranging from 100,000 to 200,000 each. Ten years ago there were but two cities in the Empire with more than half a million inhabitants, and only thirty-three with more than 100,000. At the time of the first Imperial Census in 1871, there were in Germany only nine cities with a population exceeding 100,000. Berlin had reached the half million population in 1860, but Hamburg did not reach it until 1895, and no other German city before 1905. In 1871 Nuremberg had but 82,000 inhabitants; by 1900 it had increased to 261,081. The figures of the 1910 Census give it 332,539, an increase of about 27 per cent. during the ten years.

LIST OF COMMITTEE.

Lord Sanderson, G.C.B., K.C.M.G., I.S.O. (Chairman of the Council).
Lord Blyth (Chairman of the Committee).
Earl of Aberdeen, G.C.M.G.
Sir John Anderson, G.C.M.G., M.A., LL.D.
Lord Belhaven and Stenton.
Thomas Jewell Bennett, C.I.E.
Earl Brassey, G.C.B.
Byron Brenan, C.M.G.
Richard Ernest Brounger.
Sir Thomas Fowell Buxton, Bart., G.C.M.G.
Hon. Sir John A. Cockburn, K.C.M.G.
T. A. Coghlan, I.S.O., F.S.S., Agent-General for New South Wales.
Captain R. Muirhead Collins, R.N., C.M.G., Official Secretary to the Australian Government in Great Britain.
Edward Dent.
Hon. Sir Charles W. Fremantle, K.C.B.
Sir Somerset R. French, K.C.M.G.
Right Hon. Sir George Goldie, K.C.M.G., D.C.L., LL.D.
Robert Kaye Gray.
W. L. Griffith.
Sir John J. Grinlinton.
Hon. Sir William Hall-Jones, K.C.M.G., High Commissioner for the Dominion of New Zealand.
Sir Charles Augustus Hartley, K.C.M.G., M.Inst.C.E.
Sir Clement Lloyd Hill, K.C.M.G., C.B., M.P.
Sir Francis J. S. Hopwood, G.C.M.G., K.C.B.
Hon. J. G. Jenkins.
Hon. A. A. Kirkpatrick, Agent-General for South Australia.
Sir John Cameron Lamb, C.B., C.M.G.
Sir Nevile Lubbock, K.C.M.G., Chairman of the West India Committee.
Sir Charles Prestwood Lucas, K.C.M.G., C.B.
Sir John McCall, K.C.M.G., M.D., Agent-General for Tasmania.
Hon. Sir Newton V. Moore, K.C.M.G., Agent-General for Western Australia.
Sir E. Montague Nelson, K.C.M.G.
Sir Montagu F. Ommanney, G.C.M.G., K.C.B., I.S.O.
Sir Gilbert Parker, M.P.
Sir Westby B. Perceval, K.C.M.G.
Hon. Sir Cornthwaite Rason.

Sir Frederick Young, K.C.M.G.
S. Digby, C.I.E. (Secretary).

"OWEN JONES" PRIZES FOR INDUSTRIAL DESIGN.

This competition was instituted in 1878 by the Council of the Royal Society of Arts, as trustees of the sum of £400, presented to them by the Committee of the Owen Jones Memorial Fund, being the balance of subscriptions to that fund, upon condition of their spending the interest thereof in prizes to "Students of the Schools of Art who, in annual competition, produce the best designs for Household Furniture, Carpets, Wall-papers and Hangings, Damask, Chintzes, etc., regulated by the principles laid down by Owen Jones." The prizes are awarded annually on the Report of the Examiners in the National Competition of the Board of Education.

Six prizes were offered for competition in the present year, each prize consisting of a bound copy of "The Leading Principles in Composition of Ornament of Every Period," from the "Grammar of Ornament," by Owen Jones, and the Society's Bronze Medal.

The following is a list of the successful candidates:—

McCoy, Robert, School of Art, Macclesfield, for a Design for a Woven Tapestry Hanging.

Fildes, Berengaria, School of Art, Morecambe, for a Design for Printed Silk Dress Fabrics.

Dale, Sydney, School of Art, Macclesfield, for a Design for a Printed Velvet Hanging.

Hinton, Mabel L., School of Art, Dudley, for a Design for a Stencilled Hanging.

Meggs, Evelyn, School of Art, Dudley, for a Design for a Stencilled Hanging.

Fenske, May, Polytechnic School of Art, Battersea, for a Design for Printed Muslin.

The Examiners who judged the works submitted for competition report as follows:—

"587 works were sent in for this competition, showing an increase of 146 on last year, and the general level of merit is higher than then.

"The best examples are the Woven, Printed, and Stencilled Fabrics. There is a fairly good representation of the useful class of Damasks, as well as some good Carpets and Embroidery.

"The Examiners regret to find that no examples of Designs for Furniture have been submitted."

The next award will be made in 1912, when six prizes will be offered for competition.

THE ROYAL SOCIETY OF ARTS.*

By Sir Henry Trueman Wood, M.A.,
Secretary of the Society.

IV.—The Society and the Colonies.
(1754–1847.)

It is proposed in this article to deal with the efforts which, during the first century of its existence—from its foundation in 1754 to the grant of its Royal Charter in 1847—the Society made to encourage and develop the resources of the British colonies.

During that long period our colonial empire underwent many and great changes, both of restriction and of expansion. At its commencement "His Majesty's Colonies and Plantations abroad" meant, with some insignificant exceptions, only the North American colonies† and the West Indies. Before its close the American colonies had developed into the United States, Canada had become British, Australia had been partly explored and settled, the Cape and Ceylon had been taken from the Dutch, and many other additions, in many parts of the world, had been made to the British possessions. India also—for the earlier associations of the Society with India must be included in our review—had during this period definitely become a part of the Empire, which it assuredly was not in 1754.

It was in America, and before the Declaration of Independence, that during the first twenty years of its existence the most important part of the Society's work was done. The only reference that has been noticed in the Society's Minutes or *Transactions* about this time to the West African settlements, relates to the offer of a gold medal for the importation of cotton from Africa, and though the Society was ready to extend its efforts to the East Indies, and occasionally did so, its proposals do not appear to have been welcomed by the East India Company, which had distinctly monopolistic views as regarded its possessions. For example, in 1758 it was proposed that a prize should be offered for the production of cinnamon in "our own Territories in the Island of Sumatra," but the court of directors of the Company were "under apprehensions that if so valuable an article should be produced in the island, the Dutch will use their best endeavours to get possession of it." So the proposal was dropped, as was also a similar one for the encouragement of the production of cochineal.

At one of the first meetings of the Society after it had moved into its rooms in Craig's Court, in April 1755, Lord Romney informed the members that 300 lbs. weight of raw silk had lately been brought to England from Georgia, and that the silk was of very excellent quality, equal to the best Piedmont. He, therefore, suggested that the Society, by way of encouraging the production of silk in the colony, should offer a prize for planting mulberry trees, and it was thereupon resolved that a premium "of £10 sterling money" should be offered to the person "who shall plant, and properly fence, the greatest number of white mulberry trees on his own plantation in the province of Georgia before the first day of March 1756." Prizes of £5 and £3 were added for the second and third largest number. An announcement of this prize appears in the earliest list of premiums, dated April 1756, the date being extended to March 1757.

In 1758 the nature of the offer was modified, and a payment of threepence a pound was offered for cocoons raised in Georgia, and two shillings and sixpence a pound for merchantable raw silk produced in Connecticut, Pennsylvania or North Carolina, with another shilling per pound for silk imported into England. Franklin was interested in the development of the silk industry, and acted as one of the Society's referees for distributing the awards. Certain of the colonial governors also helped by their influence and interest. The British Government gave encouragement and a bounty, and a public

* The previous articles of the series appeared in the *Journals* of June 9th and 16th, and September 22nd.

† The original from which the map on p. 1033 is reproduced is contained in Jeffrey's American Atlas, London, 1776. It is in the possession of the Royal Geographical Society. The line following the course of the Mississippi is in colour, and indicates the western limit of the British possessions.

filature was established in Georgia. The offer of premiums was continued up to 1763, by which time a sum of over £1,100 had been expended. Although at one time the promoters of the scheme seem to have been sanguine about success, the industry was never established. The absence of cheap and abundant labour may have been one reason for this, but the outbreak of the War of Independence put an end to this attempt to nurse into existence what was really not a very suitable industry.

Much the same fate attended the efforts made to start wine-making in some of the colonies, though it, too, promised well for a time, and vineyards stocked from European sources were actually established in Virginia and elsewhere. The first offer of a prize for wine appears in the 1758 list, in which the amount of £100 is promised for five tuns of good wine made at a plantation in any colony, provided that one tun was imported to London. In 1763 Mr. Charles Carter sent a dozen bottles of two kinds of wine from grapes which grew in vineyards of his own planting in Virginia. One of these samples was the product of vines brought from Europe, and the other of American wild vines. The gold medal was awarded to Mr. Carter "as the first who had made a spirited attempt towards the accomplishment of their views respecting wine in America." * Amongst other awards for wine produced in the North American colonies, two hundred pounds were given to Mr. Edward Antill in 1768, for vines planted for making wine near Brunswick, North America; the Earl of Stirling † received a gold medal in 1769, for planting 2,100 sets for wine; and Mr. Christopher Sherb got fifty pounds in 1771, for planting and cultivating vines in South Carolina, and producing wine from them.

Much greater success attended the Society's efforts to encourage the production of potash and pearlash (a rather less impure form of potassium carbonate than the crude form of the salt then sold as potash). By the prizes offered, and still more by the information supplied as to the best means of manufacture, an important industry was set up, and one very suitable for a country abounding in forests. This prize was offered in 1758, the amount being £100 for fifty tons of potash.

* Dossie, "Memoirs of Agriculture, and other Oeconomical Arts," Vol. I. p. 242.

† This was William Alexander, "Commander-in-Chief of the American forces," who claimed and bore the title after the death of the 5th Earl in 1739. He was a member of the Society, and died in 1795.

There was a large and growing industrial demand for alkali, especially for use in glass-making, soap-making and dyeing. Until the great discovery by which carbonate of soda was manufactured from common salt, the foundation of modern chemical industry (it is interesting to note that the Society's premium list for 1783 includes an offer of a gold medal for the production of "Fixt Alkaline Salts" from common salt), this demand could only be supplied by alkali procured from the ashes of plants, and to a smaller extent by imported natural saltpetre. When such ashes are treated with water the salts of potash are dissolved, and on the evaporation of the solution they are recovered. Certain plants give much larger proportions of alkaline salts than others. Plants of the genus Salicornia, or glasswort (the Eastern name of which, "kali," was the origin of the term "alkali"), give the best material, and it was known as barilla. In England large amounts were obtained by burning kelp, and this was an important industry on the Scotch and Irish coasts. All plants, however, contain more or less potash, and therefore the raw material for the manufacture was abundant in America. There were some difficulties at first in the production and purification of the salts, but these were eventually overcome by the full and detailed instructions sent out by the Society to the colonial authorities at their request.

It is interesting to note that in 1766 Robert Dossie, the able and accomplished editor of what was practically the first series of the Society's *Transactions*, was presented with a gold medal for "effectually aiding to establish the manufacture of potash in North America."

The result of the attempt to encourage the production of saltpetre in America was less satisfactory. It seems that the prize was really offered (in 1764) in the hope that it might lead to the discovery of natural sources of supply of nitrate of potash or soda, though Dossie tells us that the Society was also encouraged by reports of some new method of manufacturing the salt having been discovered in America. The old system of obtaining nitre from "nitre-heaps," mixtures of animal excreta with wood-ashes and lime, was obviously not well suited for a sparsely populated country like America, and it was not to be expected that there would be any artificial nitre produced in excess of the requirements for home consumption.

But the hope of discovering natural sources

of supply of natron,* the neutral carbonate of soda ($Na_2CO_3$10 Aq.), was perfectly reasonable. The salt existed in various forms, sometimes as an efflorescence on ground or rocks, sometimes in mineral springs or lakes, and sometimes as solid deposits in "pits" in many countries. The "soda lakes" in the Libyan desert and in Upper Egypt were known from remote antiquity. Herodotus (ii. 86) describes the use of the nitron obtained from them in embalming. The natron pits of Khaipur in Sind have long been a source of revenue to their owners, and there were numerous other places in the Old World whence the material was brought to England before the secret of making "artificial saltpetre" was purchased from the German Honrick by Queen Elizabeth. There was, therefore, every reason to believe that similar deposits might be found in the New World. Indeed, in our own days, the anticipations of the Society have been justified by the discovery of the vast nitrate fields of Chile, from which nearly all the world's supplies of nitrate of soda are now derived.

However, the hopes were not realised, and as no response was made to the offer it was withdrawn after a few years, though at a later date it was renewed, and in 1786 a silver medal was actually awarded to H. Scott, a surgeon in the East India Company's service in Bombay, for a sample of "native Indian fossil alkali." This was "a brown earth brought from Sindy." It was stated that large amounts of the earth were available, and on analysis it proved very rich in alkali. Very probably this was the first introduction to England of soda carbonate from the natron pits of Sind above mentioned, though it may indeed have been imported without its source of origin being known.

The only connection between the Society and the manufacture of iron in America seems to have been that a prize was offered for making iron from "black sand" (magnetic oxide of iron). The offer was a reasonable one, but the solution of the problem was far beyond the metallurgical knowledge of the time, and indeed, until lately, it has never been possible to treat this ore successfully. Still a certain amount of success was attained, for a gold medal was given in 1763 to Jared Eliott for malleable iron from American black sand. According to Scrivenor,* iron was first made in America in 1715, and the amount made steadily increased, until about 1776 some 4,000 tons were exported. Ten years later the amount produced in England and Wales was only 13,000 tons, the production having fallen off in consequence of the diminished supply of wood, the only fuel by which iron could be made.

With its enormous forests, America might well have supplied the English market for iron, and from time to time provisions were grudgingly introduced into Acts of Parliament with the view of encouraging the industry, but when any encouragement was given it was either so set round with limitations as to be useless, or was soon taken away at the appeal of the English iron-makers, in spite of the demands urged by those who wanted iron but were not makers. An account of the legislation from 1719 to 1769 is given by Scrivenor, and it is as little creditable to the British Government as were most of the dealings of this country with its American colonies.

The Colonial Manufactures Prohibition Act, 1750, so far encouraged the production of raw iron that it removed the duties on bar or pig iron, but it not only forbade the working up of such iron, but prohibited the establishment in America of furnaces, tilt-hammers, or slitting-mills for the purpose. England at this time was always ready to help the colonies, provided only they did not compete with her own manufacturers. Raw materials to any extent they were encouraged to provide, but manufactured articles of any sort they were not permitted to export, or even, in most cases, to produce.

A considerable amount of hemp has always been grown in England, but large quantities were imported from abroad, especially from the Baltic ports. It was thought that the North American colonies might become sources of supply, and a prize was therefore offered for American imported hemp. Soon, however, it was realised that, as there was a great local demand for hemp for rope-making, and the price was consequently higher in America than in England, it was not likely that the fibre would be sent over here, and the conditions of the offer were changed, so that it might serve to encourage the actual production of the fibre

* The word natron, never common, is now practically obsolete, though Murray's Dictionary gives an authority as late as 1876. It is, perhaps, derived from the Arabic natrūn, the Greek equivalent being νίτρον, the Latin nitrum. Our own nitre is now only used as the equivalent of saltpetre (potassium carbonate), but it was originally employed as identical with natron. Skeat suggests that the sense of the word has been changed, but it is probable that it is merely a case of a word originally used in a general sense, having its application reduced, as chemical technology became more accurate, to a specific substance.

* "History of the Iron Trade" (1854), p. 69.

without calling for its export. The scarcity of labour, however, again proved an obstacle, and though some hemp was grown, there were difficulties in obtaining labour to treat the stalks for the production of the fibre.

As regards one important application of hemp at the time, the manufacture of sail-cloth, it soon found a rival in the native American fibre, cotton, which was extensively applied to sail-making in America, before its use was ever adopted for the purpose on this side of the Atlantic. Later on, as will be seen, when

Canada became a British possession, the cultivation of hemp in that country was successfully established by the Society's efforts.

The Society expended a good deal of money in the attempt to organise a supply of pickled sturgeon from the North American colonies. It appears that there was a considerable import of this fish from Russia, and that which was brought over from the colonies was nearly as good. The attempt seems to have been moderately successful, but the demand was not very large, and no doubt the trade was a small one. The premium was first offered in 1760, and was continued for some time, various sums of £50 and less having been paid for importations on a commercial scale of the preserved fish.

The offer, made in 1768, of a reward for American isinglass, might seem more likely to have had good results, but it was dropped on an appeal from the owner of a patent* for making isinglass in England, who hoped to obtain abundant material for the manufacture from the Newfoundland cod fisheries. Dossie† tells us that these hopes were not realised, though the Society was led to abandon its offer.

The sturgeon of the American Great Lakes and rivers (*Acipenser rubicundus*) is a different species from the Russian sturgeon (*A. stellatus*), and is less abundant. Economically, however, it is equally valuable, and is now the subject of a considerable industry. The flesh is pickled, while caviar and oil are also made from the fish. The offer, therefore, of the Society, though fruitless at the time, was reasonable enough, for it only anticipated by a century or so the establishment of an important industry.

Another object on which a good deal of trouble and some money was spent, was an attempt to import myrtle wax, or, as it is now commonly called, myrtleberry wax, from North America. This is a well-known vegetable wax, the produce of *Myrica cerifera* and other species of *Myrica*, which are found in North and South America, Africa, and elsewhere. The plant is not a myrtle at all, but is allied to the willow tribe.‡ The British representative of the genus is *Myrica gale*, gale, or Scotch or Dutch myrtle, also "bayberry tallow," common in moist heathy grounds. A kind of wax can be obtained from this plant when it is boiled. Some foreign species supply wax in greater abundance, the succulent fruit being covered with a waxy secretion. The product of the American species, known as bay myrtle, or candleberry bush, had long been used, in combination with beeswax, for the manufacture of wax candles, and at the time, when there was a great demand for materials for candle-making, it was thought that the importation of such a material would be valuable, if on a sufficiently large scale. Accordingly, a prize of £20 was offered in 1759 for the importation of the material in commercial quantities. Prizes were awarded in 1760, but after that they were dropped, as it was not considered that a sufficient amount of the wax was likely to be imported; in fact, as Dossie said, the only application of the material was the "sophistication of plasters in the manufacture of them by some wholesale dealers in medicinal preparations."

In 1776 an application was made to the Society by certain coopers to give assistance in promoting the importation of pipe staves from America in place of those brought from Germany. The committee which was appointed to consider this matter found that at least £100,000 was annually paid for staves imported from Germany, and that Quebec oak made into staves would answer all the purposes of the German; but whether any practical result came of the suggestion does not appear to be known.

Such were the more important or interesting colonial products, the growth or importation of which the Society strove to promote. Amongst others of minor value may be mentioned olives, raisins, logwood, cochineal, scammony, opium, safflower, persimmon, aloes, and sarsaparilla.

Besides encouraging the production of new commodities in the colonies, the Society rendered valuable service on occasion by sending out machinery. As will be mentioned in a future article, the Society succeeded in establishing a saw-mill in England, and the result of this was an inquiry from America, where there would be much greater scope for the use of such machinery.

Accordingly, the Society paid Stansfield, the original constructor (he cannot well be called the inventor, for the machinery had long been in use in Holland and Germany), £60 for a model of his apparatus, and sent it out to America. It appears to have been useful, for

* An examination of the lists of patent grants about this date has not afforded any clue to this patent.

† Vol. I. p. 276.

‡ The myrica of Virgil (and Pliny) is not the same plant at all, but a tamarisk. When in his Eclogues (viii. 54) Virgil includes in his list of portents the production of amber by the tamarisk—

"Pinguia corticibus sudent electra myricæ,"

he was perhaps influenced by the knowledge that the tamarisk really does produce a secretion, so-called manna, the result of the action of a coccus inhabiting the tree. Hence the botanical name of one species, *Tamarix mannifera*.

"the good effects of it have been acknowledged in the strongest terms by the governor of one of the colonies and some other principal persons."* As Dossie remarks that from this model the colonists were able to make great improvements in their saw-mills, it is evident that such mills were in use in America before they had been established in England.

A gold medal was awarded in 1766 to Sam Brown, of Georgia, "For his useful observations in China, and industrious application of them in Georgia." No record has yet been found of these observations, so it is not known what they were.

The Declaration of Independence in 1774, and the resulting separation of the United States from the Mother Country, of course put an end to the attempts of the Society to develop the resources of the North American colonies, and from that date till the end of the century the attention of the Society was practically confined to the West Indies. Here a considerable amount of useful work was done. Sometimes the offer of prizes produced immediate practical results, sometimes the suggestions originated experiments and inquiry, so that ultimately useful industries were started, and valuable imports obtained.

Among the vegetable products, for the growth of which in the West Indies prizes were specially offered, may be mentioned mango, bread-fruit, olive, opium, cinnamon, nutmegs, sarsaparilla, aloe, safflower, indigo, cotton, anatto, vanilla, cloves, pepper, mace, camphor, quinine, various tinctorial plants, and ornamental woods. For several of these rewards were claimed and awarded, but in other cases the offers produced no practical result.

The main idea which directed the efforts of those who were trying to develop the West Indies was the introduction into the new lands of the West the known and tested products of the ancient civilisation of the East. Those who in the eighteenth century were working with this object were only following the lead of the earliest colonisers of America. The Spaniards introduced the sugar-cane into San Domingo before the end of the fifteenth century, and it flourished as it had never done in the Eastern lands where it was indigenous. Coffee was introduced by the French into either Cayenne or Martinique about 1722, and it soon spread to the other islands.† By 1770 or thereabouts it was a staple product of Jamaica. The Oriental bamboo is believed to have been artificially planted in Hispaniola, whence it spread to Jamaica and the other islands. Cotton was indigenous in the Western Hemisphere, though the species was different from the cotton of the East known to Herodotus, Theophrastus and Pliny, the wild tree bearing fleeces from which the Indians made cloth. The cotton grown in the islands was no doubt brought from the mainland. The orange is believed to have been introduced by the Spaniards into the West Indies, and to have been transplanted thence to Florida. Long, in his "History of Jamaica" (1774), speaks of it as growing wild in that island, but not being properly cultivated, as it was in South Carolina. The mango is said to have been first introduced from the East Indies into Brazil by the Portuguese, and to have been transplanted thence to the islands; of which more hereafter.

In continuation of these importations, the English colonists and their associates at home hoped to transplant to the tropical western islands the economic flora of India and the spice islands, especially the latter, while they were also not unmindful of the resources placed at their disposal by the recent discovery of the islands of the South Seas.

The first mention of the West Indies occurs in the Premium List for 1759, which contains a special offer of £100 for cochineal from Jamaica, though in the previous lists various prizes were included which were open to the West Indian in common with the other colonies.

The story of the introduction of the bread-fruit (*Arto-carpus incisus*), with its incidents of the mutiny of the "Bounty" in 1789, the abandonment of Captain Bligh, and the colonisation of Pitcairn Island by the mutineers, is well known.

The first suggestion that the bread-fruit might be introduced into the West Indies is said* to have come from Valentine Morris, the Captain-General of St. Vincent, who wrote in 1772 on the subject to Sir Joseph Banks, and no doubt as the result of this letter a prize was offered in 1777 by the Society. In 1786 Sir Joseph, urged by Mr. Hinton East, of Kingston, Jamaica, who was then in London, brought the matter before George III., and the result was that the expedition of which

* Dossie, Vol. I. p. 126.

† In a little "History of Coffee," by W. Law, of Edinburgh, "coffee merchant to the Queen" (1850), it is stated that the coffee plant was introduced by the French into Cayenne from Surinam in 1722, and five years later into Martinique. According to another account it was sent to Martinique direct from France, a coffee tree having been presented to Louis XIV. by the magistrates of Amsterdam.

* E. Smith, "Life of Sir Joseph Banks" (1911), p. 123.

Captain Bligh was the commander, was sent to the South Seas in the "Bounty" to collect bread-fruit trees and to transport them to the West Indies. The fullest instructions were drawn up by Banks, the ship reached Otaheite, and a number of plants were collected. All went well until the return voyage from Otaheite, when the mutiny took place, and Bligh was sent adrift in the ship's launch. A second expedition was more successful, and in 1793 a cargo of bread-fruit trees was safely conveyed to the West Indies by Captain Bligh in H.M.S. "Providence." On his return, Captain Bligh sent in a full report to the Society,* from which it appeared that over 300 bread-fruit plants had been successfully landed in Jamaica, and a like number in St. Vincent, besides a large number of other plants from the Pacific Islands. Most of these are only described by their native names, but the list includes mango, pomegranate, cocoa-nut, coffee, almond and plaintain. The gold medal was, on this report, awarded to Captain Bligh.

From reports made to the Society in 1795 by General Melville, and by Dr. Dancer in 1796,† it appears that the trees grew and flourished in the islands, and a little later similar information was received from St. Vincent. Dr. Alexander Anderson, the Superintendent of the Botanic Gardens in that island, reported fully in 1798 on the condition of the trees there, and stated that they were well established and were producing an ample supply of the fruit.‡ Later reports in 1802 and 1803 were equally satisfactory, and in 1807 he writes that though it is one of the most valuable productions sent to the West Indies, it is not appreciated at its proper value. He adds that it is said that the negroes did not like it, but that he did not believe this. Its want of popularity he attributes to the apathy of the planters. It may be added that in 1799 a gold medal was awarded to S. Mure for a plantation of bread-fruit trees in Jamaica, and two gold medals were given in 1802 and in 1803 to the Hon. Joseph Robley, the Governor of Tobago, for his plantation of bread-fruit trees in that island.

In 1760 a gold medal was offered for the introduction of the mango into the West Indies, but after three years the offer was dropped. Twenty years after this, in 1784, Walter Maynard, of Nevis, wrote to the Society that in 1770 he had brought some young mango plants from the Island of Bourbon to St. Vincent, that they had fruited there, "and are now propagated in almost all the West India islands." The statement was supported by evidence, and it was said that one of the plants had been given to Dr. Young, the Superintendent of the Botanic Gardens at St. Vincent.* It appeared, however, that this was not the first introduction of the mango, for on inquiry being made of Mr. Joshua Steele, a member of the Society, and the President of the Barbados Society of Arts, that gentleman sent the Secretary an account of an ancient mango tree then existing in a plantation in Barbados, called "The Guinea."† This tree had, it was believed, been imported and planted by Edwin Lascelles in 1742 or 1743, but it bore no fruit till 1761. It is very likely that this was the tree mentioned by Dossie‡ as having been brought from the Brazils, where the mango was said to have been introduced from the East Indies by the Portuguese missionaries. From this tree others had been propagated, and were growing in different parts of the island. It is clear, therefore, that the mango was well established in the West Indies in 1784. It has been said that Lord Rodney introduced the fruit in 1782, but this cannot be true. One of Lord Rodney's captains (Captain Marshall, of the "Flora" frigate) certainly captured a French ship, carrying some economic plants from Bourbon to Hispaniola, and these plants were sent to Jamaica. It is quite likely that mangoes may have been included in the cargo. It is also possible, and by no means unlikely, that the French may have introduced the mango into Martinique, with other plants they sent there, before it was established in any of the British islands.

Among the plants whose destination was thus altered, were some young cinnamon trees, and this appears to have been the first introduction of the Eastern cinnamon to Jamaica, for which the Society had offered a prize as far back as 1760, though the Guadaloup cinnamon is mentioned by Dr. Young. Dr. Dancer, the Superintendent of the Jamaica Botanic Gardens, writing in 1789 to the Society, gives an account of the condition of the cinnamon trees then growing in the island, and describes them as flourishing, but not very numerous.§

§ *Transactions*, Vol. VIII. pp. viii. and 207. See also Vol. IV. p. 22).

Indigo was at one time largely cultivated in Jamaica, but heavy import duties imposed by Parliament* destroyed the industry, the revival of which seems to have been stimulated by the Society, not only in Jamaica, but in the other islands; for in 1778 a gold medal was awarded to John Robley for growing and manufacturing indigo in Tobago. The account given in the *Transactions* † states that in one year as much as 10,000 lbs. of good indigo was raised on a plantation formerly devoted to sugar-planting. The indigo was presumably the indigenous Mexican and Guatemalan variety, *I. disperma*, not the East Indian sort, *I. tinctoria*. Four years previously, in 1774, a gold medal had been awarded for the production of indigo in East Florida.

A gold medal was offered in 1768, and the offer was continued till 1777, for the best specimen of cotton equal to "the best Brazilian," produced in any of the American colonies, but it appears not to have attracted any claimants till 1778, when it was awarded to Andrew Bennet, of Tobago, for cotton grown in that island.

A prize offered for logwood from British colonies was abandoned, because it was found that the wood produced in Jamaica was inferior to native Honduras and Campeachy logwood, and besides that the cultivation of logwood in the sugar islands was unnecessary and undesirable, since it became practically a troublesome weed.

A great deal of valuable work was done in the West Indies by the establishment of botanic gardens, and they were aided in various ways by the Society. In one of the earliest Premium Lists, that for 1760, it is suggested that land should be allotted in the colonies for "gardens or nurseries for the making experiments in raising such rare and useful plants as are not the spontaneous growth of the kingdom or of the said colonies," and it is added that if the colonial legislatures, or "other incorporate bodies," would help to establish such gardens, the Society would provide "proper premiums" for plants raised in them. This undertaking was liberally and fully carried out. The suggestion soon bore fruit. The first of these gardens was started in St. Vincent in 1765 by General Melville, the Governor-General of the "Southern Caribbee," or Windward Islands, a member of the Society, whose attention was attracted by the notice.‡

* Long, "History of Jamaica," Vol. III. p. 680.

† Vol. II. p. 233.

‡ Dossie, Vol. III. p. 196.

Dr. George Young, an army surgeon in the island, took charge of the gardens. He was acting as superintendent of them in 1774, and in that year sent the Society a full report* on the gardens, for which he received a gold medal. For a time the island was in possession of the French, but the garden was kept up. In 1784 St. Vincent was restored to Great Britain, and Dr. Alexander Anderson took charge of the garden. In 1798 he received a silver medal from the Society for an account of the plants cultivated in it, and in 1802 he was awarded a gold medal for the "culture of cloves and cinnamon." He was a corresponding member of the Society, and a constant contributor to the *Transactions*. He died in 1811.†

In 1775, according to a letter written by Dr. Hope (the Professor of Botany at Edinburgh) to Sir Joseph Banks,‡ a botanic garden was founded in Jamaica. Dr. Clarke was appointed superintendent, and he introduced the camphor-tree and sago palm.

Later, Dr. Dancer had charge of this garden. He received the Society's silver medal in 1790 for his account of the cinnamon tree in Jamaica above referred to. He was a valued corresponding member, and, like Anderson, a frequent contributor to the *Transactions*.

In the year 1793 the Society offered 100 guineas for the establishment of a botanic garden in the Bahamas. This offer was repeated annually up to 1802, but no response having been made, it was then withdrawn.

The Society does not seem to have had any association with the botanic garden in Trinidad, but in 1831 David Lockhart, "Botanical Gardener to the Government of Trinidad," received a gold medal for the successful culture of nutmegs and mace in that island.

In the case of the West Indies, as with the North American colonies, useful service was rendered by the transmission of seeds, samples, etc., the provision of machinery and models, and the supply of information.

A good deal of correspondence has been preserved in the old guard-books of the Society, showing the anxiety of the colonial officials and others to obtain such information, and the readiness of the Society to collect and supply it, and it appears quite certain that the aid thus rendered

* Dossie, Vol. III. p. 260.

† In 1825 the Rev. Lansdown Guilding published at Glasgow an account of the St. Vincent Garden from its establishment to 1825. The book contains a good deal of information about Anderson and his work. A copy is in the Society's library.

‡ E. Smith, "Life of Sir Joseph Banks" (1911), p. 122.

was fully appreciated. That the Society was so successful in this branch of its work was due to the fact that it was in constant communication with the officials on the spot, and with those colonial residents who took an interest in the economic progress of the islands, and could supply information as to local requirements. On the other hand, it had the command of the best advice from scientific men at home who could provide the requisite botanical and chemical knowledge (so far as such knowledge existed at the time), and from manufacturers and traders who knew what products would best find a market in Europe. The staple products of the islands were not considered to need encouragement or help, and so we read little in the Society's colonial records about sugar or tobacco. The object was to discover new sources of revenue, to introduce fresh industries and new economic plants, and there is no great reason for surprise if we find that many of the suggestions bore little or no fruit. On the whole, the efforts of the Society to aid colonial progress during the first fifty years or so of its existence were well applied, and had very considerable practical results.*

In the early years of the new century the interest which had been taken in the West Indies, so far as relates to the introduction of new economic plants, grew less. This may have been partly due to the death of those men in the islands who had devoted themselves to the work; for when Young, Dancer and Anderson had all passed away, the Society lost its most important correspondents, and there were none to take their place. But beyond much doubt the real cause was the dislike of the planters to anything which interfered with the cultivation of the sugar-cane. Sugar was firmly established as the staple industry of the islands; it was successful and profitable, and the planters not only did not desire, but were inclined to oppose, the introduction of any other crop which might interfere with its cultivation. In one of the letters which Anderson wrote to the Society in 1807, he refers to this feeling. The result was that the efforts of those on this side who had tried to encourage the introduction of new economic plants were relaxed, and though the special offers of prizes for the growth of West Indian products remained in the Society's lists, the awards became fewer, though some were occasionally claimed. For instance, in 1824 a sum of fifty guineas was presented to Francis Le Cadre for his plantation of clove trees in Trinidad.

As before stated, the Society in its early years had but little connection with India and the East, though on occasion it was consulted by the East India Company, and information was supplied to it by the Company. A few, but not many, prizes were offered for the productions of the British possessions in the East Indies, and only a small proportion of these were claimed. The award of a gold medal in 1792 to George Unwin "for reviving the trade of tin from this country to India and China" was intended as an encouragement to British rather than to colonial or Indian industry, but it is curious, because it was after the importation of Eastern tin to Europe had begun. It was about 1787 that the first samples of tin from Banca, in Sumatra, were brought over, and a source of supply of the metal made known which soon interfered with the monopoly possessed by the Cornish mines. Before many more years the course of trade was in the other direction, and large amounts of tin were being brought from Banca to England. From 1800 to 1821 a prize was open for the importation of "Bhaugulpore cotton"—"from which clothes are made in imitation of nankeen, without dyeing" — but without any effect. This offer was at first confined to the "British Settlements in the East Indies," but it was afterwards extended to the other colonies. In 1792 a silver medal was presented to Mrs. Anstey, of Madras, for the introduction of cinnamon in 1781. In 1801 Andrew Stephens, of Calcutta, had a silver medal for "Lake from stick lack." The award of a prize for Sind natron in 1786 has been mentioned previously on page 1032. About the end of the century, however, a greater interest seems to have been aroused in Indian matters on the part of the Society, and perhaps the Company were more ready to avail themselves of such advantages in the way of technical advice and publicity as the Society was able to supply.

It is probable, too, that the new interest in East Indian matters was, to a large extent, due to Dr. William Roxburgh, the great Indian botanist, who was Superintendent of the Calcutta Botanic Gardens from 1793 to 1813. Roxburgh became a corresponding member of the Society

* From the account published in 1783 of the amounts awarded in premiums up to that date, it appears that £2,785 13*s*. 8*d*. had been expended, and fourteen gold medals awarded by the Society as rewards in the colonies. Of this amount, £175 was spent for importing earth nuts, myrtle wax, sturgeon, and zebra wood; £50 for making indigo, iron, and saltpetre; £1,666 for planting vines and mulberry trees, and producing silk and cotton; and £895 for the manufacture of potash and pearlash.

in 1797, and from that date until the time of his death in 1815 he was constantly forwarding communications, most of them of considerable interest and value, to the Society. In 1798 he sent the first specimen of Malayan rubber to the Society, having discovered the source of the rubber in the tree which he described and named *Ficus elastica*. Caoutchouc had been known since the middle of the eighteenth century, but only as a curiosity, and as useful for rubbing out pencil marks. Priestley in his book on "Perspective" (1770), refers to this use, and mentions that the price of a block half a cubic inch in size was three shillings. The sources of rubber in Para, and the method of collecting it, were well known; samples frequently reached Europe, and the gum was described to the Paris Academy of Sciences by La Condamine, who had been sent out by the French Government to measure an arc of the meridian near Quito. Its properties were afterwards investigated by Fresnau, who submitted a memoir on the subject to the French Academy in 1751. It may be added that at a later period rewards were offered by the Society for caoutchouc from Africa, the West Indies, and elsewhere, but without any result.

Roxburgh was also the first to introduce to Europe the important fibre ramie (now classified as *Boehmeria Nivea* var. *tenacissima*, but named by him *Urtica tenacissima*). He reports* that he had plants growing in 1804 in the Botanic Gardens, Calcutta, from Malay seed. Nine years later, in 1815, a silver medal was awarded to Captain Cotton, for growing ramie (which is termed "calooee hemp") in Bengal, apparently from plants or seed obtained from Sumatra by Dr. Roxburgh. Captain Cotton's communication to the Society is probably the first account of the plant and its treatment.† From that date up to the present the development of ramie has formed a constant topic of discussion at the Society of Arts. In 1860 Dr. Forbes Watson prophesied that the fibre from this and other plants of the nettle species would occupy a place second only to that of flax. Dr. Watson's prophecy has perhaps not yet been quite realised, but it is certainly on the way to realisation, as the various difficulties of manufacture are being overcome.

Various other communications were made by Dr. Roxburgh to the Society, but none of them have quite the same present interest as the two above referred to. He received a gold medal in 1805, and another in 1814, for his communications on East Indian products, and on many other occasions he was formally thanked by the Society for the valuable information he supplied to its *Transactions*. A portrait of Dr. Roxburgh forms the frontispiece to Vol. XXXIII. of the *Transactions*, and the same volume contains a memoir of him.

* *Transactions*, Vol. XXIV. p. 148.

† *Ibid.*, Vol. XXXIII. p. 182.

In the year 1843 Dr. William Montgomerie, of Singapore, sent to the Society some samples of gutta-percha, and in the same year Dr. José D'Almeida presented some specimens to the Royal Asiatic Society. Nothing was done with D'Almeida's specimens, but those of Montgomerie were examined by the Joint Committee of Chemistry, Colonies, and Trade, which resolved "that this substance appears to be a very valuable article, and might be employed with great advantage in many of the arts and manufactures of the country." This resolution was passed at a meeting on January 23rd, 1845. At the ordinary weekly meeting on March 19th, the Secretary, Mr. Francis Whishaw, described the specimens and showed a piece of pipe and a lathe-band made by him, which were afterwards exhibited at the Great Exhibition of 1851. He also produced some good impressions of medals. It was at this meeting that Sir William Siemens became acquainted with the new material, and obtained a sample, which was subsequently sent to his brother Werner in Berlin, to try whether it was suitable for insulating telegraph wires. In June of the same year the gold medal was awarded to Dr. Montgomerie for his discovery. He had previously (in 1842) received a gold medal from the Society for the cultivation of nutmegs in Singapore.

Nothing was said or apparently known about D'Almeida, on whose behalf a claim was made many years later, in 1858, by his son, whose letter will be found in the *Journal*.* Such evidence as there is appears to show that in point of time Montgomerie was the first to realise the value of the gum, because in March 1843 he had already submitted samples of gutta-percha to the Bengal Medical Board before sending the samples to London. But whichever of the two claimants may have been first to suggest the practical value of gutta-percha, there is no doubt that it was Montgomerie's action which first introduced it to public knowledge, and rendered its practical applications available.

The subject has been very thoroughly worked

* Vol. VII. p. 20.

out by the late Dr. Eugene Obach in his Cantor Lectures on "Gutta-percha." Many further details will be found in the report of his first lecture,* and there is much other information about the early history in the appendixes which were added by Dr. Obach when the lectures were republished.

As far back as 1788 Sir Joseph Banks suggested to the court of directors of the East India Company the practicability of cultivating the tea plant in British India; but nothing came of the suggestion, probably because the H.E.I.C. then had the monopoly of the China tea trade, and saw no advantage in starting a competition. In the year 1822 a gold medal was offered by the Society to the person who should communicate, from information obtained in China, the best and most authentic account of the culture of the plant or plants, the leaves of which furnish the different kinds of tea, together with the method of gathering, drying and otherwise preparing the leaves. This offer was supplemented in the following year by one of the gold medal or fifty guineas to the person who should grow and prepare the greatest quantity of China tea of good quality, not being less than 20 lbs. weight, in the island of Jamaica, or in any other British West Indian colony, and should import the same into Great Britain. The same premium was offered for the colonies of the Cape of Good Hope, Mauritius, and New South Wales. These offers, opportune as they certainly were, seem to have been in advance of their time, for they produced no response. Twelve years later, in 1834, when the East India Company's monopoly had expired, and there was no longer any objection to a rival to the China trade, it was realised that it was not safe or desirable that England should be dependent on China for its supplies of tea, and steps were taken to ascertain the possibilities of raising tea in India. A committee was appointed by the Governor-General, Lord William Bentinck, with Dr. N. Wallich, the successor to Dr. Roxburgh as Superintendent of the Calcutta Botanic Gardens, as its secretary. The existence of wild tea in Assam had been discovered "perhaps originally by Major Bruce, subsequently in Manipur by Mr. Scott" (Watt) between 1821 and 1826, but no attention had been paid to the discovery, and China plants were imported. In the meantime the Assam tea tree had been rediscovered by Captain Charlton and Captain Jenkins. The general belief is that the introduction of the Chinese plant was a mistake, and that the hybrids which were produced were inferior to the native Indian shrub. Eventually tea plantations were established in Assam, and in 1836 Mr. C. A. Bruce was appointed superintendent. Samples of the tea were sent to England in 1838, and were presented by the H.E.I.C. to the Society. In 1839 a Committee of the House of Commons on the subject reported favourably on Mr. Bruce's work, and in consequence of this the gold medal offered seventeen years before was awarded to him in the session 1839–40, "for his meritorious services in discovering the indigenous tea tracts and cultivating and preparing tea in Assam." There seems no doubt that Mr. Bruce's work was well deserving recognition, but it seems equally certain that he was in no sense the discoverer of the tea plant or "the indigenous tea tracts."*

In 1831 Dr. Wallich, the Superintendent of the Calcutta Botanic Gardens, presented through the court of directors of the East India Company, a very fine collection of Indian woods, containing 456 specimens,† and for this in the following year he was presented with a gold medal. Dr. Wallich, who was a corresponding member of the Society, had previously sent some valuable communications on Indian economic plants, which appeared in the Society's *Transactions*. In 1834 another collection of Indian and other woods (comprising 452 specimens) was presented by Captain H. C. Baker, of the Bengal Artillery.‡

Ceylon was not a British colony till 1802, when it was ceded to Great Britain by the Treaty of Amiens. It seems to have received but a small share of the Society's attention. In 1815 a silver medal was awarded to Thomas Hoblyn for the introduction of cocoa-nut oil from the island, and in the following year he received a gold medal for inventing and introducing into Ceylon a machine for decorticating rice. This machine, as well as a press for the production of the oil, is described in the *Transactions*.§ The decorticating machine appears to be the first of its kind, at least the earliest patent for such apparatus is dated 1819; it anticipates in many of its details the principles on which later

machines for the purpose were based, especially the application of adjustable mill-stones for husking the rice. Before this invention the operation was carried out with a pestle and mortar, the result being that the grains were, to a large extent, broken and rendered useless.

For Canada, it cannot be said that very much was done by the Society. When the Society began its colonial work, Canada was still French; it was only partly explored and quite undeveloped, and for some time after it passed under the British flag there were few industries of value, except the exportation of furs. Yet, as time went on, and the country was settled, the Society endeavoured to do its duty to what was then the greatest colony, or group of colonies, belonging to Great Britain, and much of interest about Canada is to be found in the *Transactions*. In the early part of the nineteenth century a strong effort was made, and with a good deal of success, to encourage the growth of hemp, a fibre then in great demand for naval purposes, as it was practically the only material available, not only for ropes, but also for sails. In 1801 various medals and prizes were offered for the growth of hemp in the two Canadas, Nova Scotia and New Brunswick, and these were continued for thirty years. Many of these were awarded. In 1804 a gold medal was awarded to J. W. Clarke, a similar medal and 100 guineas to Jacob Schneider, and a silver medal to Daniel Mosher. In 1806 silver medals were awarded to Philemon Wright, Frederick Arnold and Joshua Cornwall, also a prize of twenty dollars to G. Ward. In 1809 a silver medal "set in a broad gold border" was given to C. F. Grece, and a silver medal to Mr. Durand. All the above were Canadians. It is stated in the *Transactions* that, as a result of the attention which had been drawn to the subject by the Society's announcements, a considerable trade in hemp had been set up, and a large amount of fibre imported.

The offer of a prize for the growth of hemp was a little later extended to the other colonies, and there was added a reward for the discovery of a good substitute. In announcing this award in 1823 a note was added, drawing special attention to the *Phormium tenax*, or New Zealand flax, of which specimens had lately been brought to England. The importation of the fibre rapidly extended, and between 1828 and 1832 no less than £50,000 worth was shipped to Sydney alone.* The present annual value of the export from New Zealand is £307,000.

It does not appear what prompted the offer in 1792 of a gold medal for the discovery of a "North-West Passage by land from Canada to the South Sea." It is possible that the disputes between Spain and England about Nootka (now St. George's) Sound (on the west coast of Vancouver) and the adjacent regions, which nearly led to war but were settled by the Treaty of the Escurial in 1790, may have directed public attention to those little-known lands. More probably it was reported that attempts were being made to explore the north-west of Canada, and the Society wished to encourage them, and to identify itself with them. However, soon after the offer was made, Alexander Mackenzie completed the adventurous journey which brought him to the shores of the Pacific near the present boundary between Alaska and British Columbia. After exploring much of the north-west, and discovering the great river which now bears his name, he started in 1789 from Lake Athabasca to make a passage to the coast, which he reached in June 1793*. The richly-deserved gold medal was awarded to him in 1800, a rare, if not a unique, instance of an award made by the Society for exploration alone. About this time Mackenzie came to England, and in 1802 he was knighted by George III. He died in 1820.

In 1807 a silver medal was awarded to William Bond for a communication printed in the *Transactions*† containing information about Canadian industries and resources.

In 1816 Lieutenant-Colonel Joseph Bouchette, Government Surveyor to the Commission for settling the boundaries between the British colonies in North America and the United States, presented an extensive survey or map of Canada to the Society, for which he received the gold medal.

Mr. William Green, secretary of the Literary and Historical Society of Quebec, communicated to that society in 1827 a paper on colouring materials produced in Canada. The paper and a box of colours prepared from these materials were sent to the Society of Arts at the instance of the Earl of Dalhousie, Governor of Canada, and the Society in 1828 awarded a gold medal to Mr. Green for the pigments, which consisted of certain ochres and lakes, with some

* Morris's Cantor Lectures on Commercial Fibres (1895). *Journal*, Vol. XLIII. p. 923.

* A brief and singularly modest report of his journey by Mackenzie himself appears in the *Transactions*, Vol. XVIII. p. 289.

† Vol. XXV. p. 147.

colours of vegetable origin. They were pronounced by the authorities to whom they were referred for examination to be good, though perhaps the influence of the Governor-General had as much to do with the award as the importance of the products.

The first reference which has been discovered in the *Transactions* to the Australian colonies occurs in the volume containing the list of premiums for 1820, when two gold medals were offered, one for the greatest quantity of fine wool imported from New South Wales, and one for the finest sample of wool from the same colony. It is probable that the offer was prompted by the knowledge that Australian wool was being shipped to England, for in 1822 both medals were claimed by John McArthur, the "Father of New South Wales," and the founder of the Australian wool trade. McArthur had imported merino sheep from the Cape in 1795, and from that time he had devoted himself to the growth of wool on land near Sydney, which had been granted to him for the purpose by the Government. Whether this was his first consignment to London does not appear from the account of his labours given in the *Transactions*, but it amounted to over 15,000 lbs., and so complied with the conditions of the Society's offer. It is clear that the importation was in no sense the result of the offer, but the award of the medals, the report made by the Society on the high character of the wool, and the publicity gained by the account contained in the *Transactions*, appears to have helped considerably in making known the new and important source of supply thus opened up. At the instance of the Society, some cloth was made from the wool, and a silver medal was given to the manufacturers, Starkey, Buckley & Co., of Huddersfield.*

In the same year, 1821, a silver medal was given to John Raine for the importation of wool from Van Diemen's Land.

In 1824 a second gold medal was awarded to McArthur, and also a silver medal to Hannibal McArthur, a nephew of John, for the importation of the next greatest quantity of fine wool. Besides these, there were some prizes to manufacturers for cloth made from the wool, and after this the offer of rewards was dropped, the trade in Australian wool being established on a firm basis.

In 1822 a gold medal was offered for the importation of "the finest wine, not less than twenty gallons, of good marketable quality, made from the produce of vineyards in New South Wales." For some years this produced no response, but in 1833 a silver medal was presented to Mr. Gregory Blaxland for wine, the produce of his vineyard at Paramatta. "On examination by the Committee, it appeared to be a light but sound wine, with much of the odour and flavour of ordinary claret . . . though the present sample, from the inexpertness of the manufacture and the youth of the vine, is by no means of superior quality, yet it affords a reasonable ground of expectation that by care and time it may become a valuable article of export."

From a memorial to Governor Macquarrie from Mr. Blaxland, in October 1818, printed in the *Transactions*,* it appears that he was preparing his land for a vineyard in September 1816. He had really been anticipated by McArthur, who had started a vineyard, and had also planted olive-trees, some years before.

In 1828, a second medal, this time a gold one, was presented to Mr. Blaxland for a pipe of wine, the produce of his vineyard in 1827. "On tasting the samples, it was the general opinion that both of them are decidedly better than the wine for which, in 1823, Mr. Blaxland obtained the large silver medal of the Society, and that they were wholly free from the earthy flavour which unhappily characterises most of the Cape wines."

In 1824 the sum of thirty guineas was given to Mr. T. Kent, for preparing and importing from New South Wales extract of mimosa bark for the use of tanners, and in the following year (1825) a gold medal was awarded to Messrs. Petchey and Wood for similar material from Van Diemen's Land. In 1824 the thanks of the Society were presented to Mr. R. W. Horton, M.P., Under-Secretary for the Colonies and Vice-President of the Society, for sundry articles from New South Wales which he had presented.

There were a few, but not very many, other prizes to Australia. In 1830 a gold medal was voted to Sir John Jamison, President of the Agricultural Society of New South Wales, for his method of extirpating the stumps of trees in order to clear forest land for cultivation: and in 1834 a silver medal was awarded to James King, of Sydney, for his discovery of a sand in New South Wales, which was reported upon by Apsley Pellatt as being eminently fitted for the manufacture of the finer kinds of glass.

The award in 1775 of a small prize to a resident in Minorca for growing silk in that island is of interest, as reminding us that for

* *Transactions*, Vol. XL. pp. xiii. and 230.

* Vol. XLI. p. 236.

a brief period (1769-1782) Minorca was subject to this country, and was therefore included in the list of British colonies. After Malta was taken, in 1800, it also became eligible for the Society's awards, and so in 1811 a prize of a gold medal or fifty guineas was offered for Maltese silk. The offer was extended in 1819 to the "Isle of France" (Mauritius), which had been taken in 1810, possession being confirmed to England by the Treaty of Paris in 1814. The medal for Mauritius was taken in 1824 by M. de Chayal, who had been entrusted in 1815 with some silkworms' eggs obtained from Bengal by the Governor of the island, Sir R. T. Farquhar. The silk sent to London was reported on as being of good quality, but not first-class. In the Session of 1825-6 a gold medal was awarded to M. Barbé, of Mauritius, for the importation of cocoa-nut oil.

In 1822 an attempt was made to foster the growth of the vine at the Cape, which had then been definitely British about eight years, and a gold medal was offered to the person who should import the finest wine made from the produce of vineyards at the Cape of Good Hope, or the parts adjacent. It was announced that this premium was not offered for the sweet or Constantia wine, but to encourage the improvement of the vineyards more recently established. Viticulture had been introduced by the Dutch settlers in 1653, and developed by the Huguenot refugees in 1688. The premium was awarded in 1827 to Francis Collison, who stated that about three hundred pipes of the same quality had been sent by him for sale in the London market. "The wine was examined at the Committee by dealers and other competent judges, and was considered by them to be far superior to the Cape wines in general. It is free from the unpleasant, earthy flavour by which such wines are usually characterised, and was considered to bear a near resemblance to that made at Teneriffe."

SOME POINTS CONCERNING THE TREATMENT OF WHEATEN FLOUR.*

At the Leicester and Winnipeg meetings of this Association the author dealt with some phases of the complex questions concerning the quality of wheaten flour. Great importance must be attached to "strength," a flour's capacity for making big, shapely, and therefore well-aerated loaves. The nice appearance of food is a factor affecting its dietetic value. The whiteness of bread depends to a very great extent upon the "strength" of the flour used, for the good appearance of bread depends very largely on the perfect aeration of the loaf. "Strength" does not depend upon any one factor. A flour with a high protein-content is not necessarily strong. A flour with a low protein-content is probably, but not necessarily, weak.

The size of the loaf depends upon the production of sufficient gas during fermentation, more particularly during the later stages, and upon the gas-retaining capacity of the dough. The yeast must have a sufficiency of sugar, nitrogenous and mineral foods in forms which it can assimilate. Flour itself does not contain sufficient sugar for the requirements of the yeast. As a general proposition it is true to say that flour made from wheats harvested in moist atmospheric conditions yield as a result of diastatic action during panary fermentation a sufficient quantity of sugar, those harvested in hot dry conditions do not. The yeast requires its nitrogenous food in a very simple form. Flours containing a very high percentage of nitrogenous matter do not necessarily provide a sufficiency of nitrogenous yeast-food. It is believed that yeast can obtain all the mineral matter it requires from flour, but there are cases in which the addition of mineral phosphates does increase the yield of gas in panary fermentation conducted under commercial conditions. A flour may possess a high percentage of gluten, but unless it yields in fermentation sufficient gas to overcome the great and variable leak, and thoroughly to inflate the dough in the latest stages of the breadmaking process, it would be accounted weak.

Furthermore, a flour may yield more than sufficient gas at all stages of fermentation and may even possess a high percentage of nitrogenous matter and yet produce very small loaves. Dr. Hardy, at the Winnipeg meeting of this Association, showed that gluten loses its tenacity and ductility if it be deprived of its electrolytes. Professor T. B. Wood has demonstrated the profound influence which very dilute solutions of acids, alkalis, and salts have on the physical characteristics of gluten. It has been found that additions of very small percentages of salts natural to flour or wheaten ash do increase the size of the loaf, even though the production of gas in fermentation be unaffected or actually diminished.

The author came across a case in which the mere addition of water, if made at a time substantially prior to dough making, increased the strength of the flour to an extraordinary extent, even though the yield of gas in fermentation was not appreciably increased thereby.

He therefore, with the assistance of his colleague, Mr. A. G. Simpson, made an investigation of the changes produced, the results of which were set forth in detail. The most striking change in the flour itself appears to be the transformation of organic phosphorus compounds into inorganic. As part of these investigations, it has been found

* Abstract of a paper read by Mr. A. E. Humphries before the Chemical Section of the British Association at Portsmouth, 1911.

that during the process of baking a large proportion of these compounds becomes inorganic.

British millers nowadays obtain their raw material from all parts of the world, a multitude of varieties being raised in environments ranging from arctic or semi-arctic to tropical or semi-tropical. The climatic conditions in most districts also vary greatly from season to season. From such extremely diverse and variable materials they have to produce flours of uniform qualities. It is therefore right and proper that they should be allowed to make use of the advances in chemical knowledge in the treatment of wheats and flours. Sometimes the desirable treatment can be limited to the adjustment of water content, nature herself being thereby enabled to effect the necessary changes.

Sometimes the addition of water fails to bring about these changes, or for various reasons it is undesirable to raise the water content sufficiently, and in such cases the addition of diastatic bodies, nitrogenous yeast-foods and salts natural to wheat or wheaten ash is desirable and should be permitted. But inasmuch as such permission might be abused, a board of reference, consisting of highly qualified physiologists, chemists, and business men, should be established, to whom all such processes and additions should be submitted, and to whom millers and bakers should be responsible in such matters.

TOMATO PRESERVING IN FRANCE.

The preserving of the tomato is an important industry in the south of France and Italy, where the use of this fruit in cookery is far more general than it is in England and more northern countries. On the French Riviera tomato packing and preserving is carried on, on a considerable scale, during the summer months in small factories.

In a typical establishment at Antibes, about twelve miles west of Nice, employing three men and eight women, capable of dealing with twenty tons of the fruit per day, two different processes are carried on, viz.—first, the packing of tomatoes in slices (*tomates à moitié*); second, the manufacture of the paste, or *purée*, which is also put up in tins.

The first is a very simple operation, and is comcommenced as early as possible in the season, that is to say, as soon as the fruit is sufficiently plentiful and cheap.

The tomatoes are cut into halves, and slightly pressed between the fingers to get rid of the seeds and excess of liquid. They are then packed in tins containing one kilogram (about 2½ lbs.) each, at the rate of about sixteen halves of a medium-sized tomato to each tin, which is then filled up with a solution of common salt and water, of a density of 3° by the salinometer. The tins are then hermetically closed.

The sterilisation is effected by placing the tins in a *bain-marie*, heated to boiling-point for about two hours. The tins are placed in a sort of cage suspended from a pulley running on a rail above one of the four open boilers into which the cage can be lowered. During the busy season it is possible to shorten the time necessary for sterilisation by the use of a closed vessel, termed "autoclave," in which the tins are heated under pressure to a higher temperature than is the case with the open *bain-marie*. By means of this apparatus the time necessary for sterilisation can be reduced from two hours to one hour when heated to 105° C. (221° F.); three-quarters of an hour to 110° C. (230° F.); half an hour to 112° C. (233° F.) and even to twenty minutes if heated to 115° C. (239° F).

The preparation of the paste or *purée*, is usually commenced as soon as the fruit is plentiful, and the price as low as four to five francs per hundred kilogs (1*s*. 8*d*. to 2*s*. per cwt.).

The fruit is emptied into the hopper of a squeezing machine (similar to those used for crushing grapes) placed above an open boiler, into which the crushed tomatoes fall. This boiler is capable of holding 3,000 kilogs (about three tons) of pulp. The operation of boiling facilitates the separation of the seeds and skins. The boiled pulp is drawn off from the bottom of the pan into vats.

The next operation is the removal of the seeds and skins. This is done in a cylindrical strainer, into which the pulp is poured. Here it is kept constantly stirred by rotary *malaxeurs*, or stirrers, which force the pulp against the perforated sides of the cylinder, whilst the skins, seeds and refuse fall into a receiver.

The strained pulp, or *purée*, is next heated in smaller pans, having a capacity of about 250 kilogs (about 5 cwt.) each, until the right degree of concentration is obtained. The finished *purée*, or paste, is put up in tins of various sizes, ranging from one-tenth kilog. to one kilog. in capacity. After being closed hermetically the tins are sterilised in a *bain-marie* at boiling-point 212° F. for about three-quarters of an hour.

During a busy season, when time cannot be spared for packing a large number of small-sized tins, it is customary to store up a certain quantity of the paste in ten kilog. (22 lbs.) tins. The sterilisation of these store tins requires about two hours. These are re-packed into the small sizes as required during the slack season.

Formerly it was the practice to bottle the *purée*, but of late years, owing to competition by Italian firms, tins are used exclusively.

An inferior quality of tomato paste is prepared from the skins which, after being boiled with a certain quantity of water, are passed through the strainer. The *purée* so obtained, with the addition of salt, is concentrated by boiling and put up into small casks. It is supplied in this form chiefly to the small retailers.

An excellent preserve can also be prepared from tomato *purée* by boiling it with an equal weight of sugar, and adding powdered ginger and the juice and grated rinds of lemons to taste.

This, however, is not made on a commercial scale in factories, but only as a dainty in private houses.

THE FRUIT INDUSTRY OF CUBA.

Cuba has a wide range of fruits, some of which are very strange to the foreigner. The plum (ciruela) grows directly from the branches of the tree with no stems. The fruit is somewhat astringent, which however is not disagreeable when one is accustomed to it. The mango pertains to the peach family, the trees grow to a large size and bear a fruit which has a shape similar to a peach but is more oblong. The peel is smooth and thick and is easily removed. The fruit has a large seed covered with a fibrous growth which threads itself through the meat, is very luscious and very much prized, but many persons do not like it because of the slight taste of turpentine in it. The aguacate, or alligator pear, grows to perfection, and is used for salads. In size and shape it is not unlike a large pear. The sugar apple is very sweet, with mealy sugary interior. The sour sop (guanabana) is of the same family as the sugar apple. It is used largely in the preparation of refreshing drinks, in ices and ice-cream. The sapodilla (zapote) is a flat round fruit, about the size of a golf ball, and in colour resembles an Irish potato. There are several varieties of this fruit. The caimito is a combination of the plum and the fig. Some caimitos are green, and others have a purple exterior. They are very palatable, and are filled with a soft jelly-like substance with an agreeable juice. The mamoncillo is a small round, green or russet fruit about the size of a large marble, filled with a very acid juice. It has very little meat, as the large seed leaves little room for the juice and the yellowish meat which surrounds it. This fruit makes a delicious drink. The guava is used for making exceptionally fine jellies, marmalades and preserves. The peel is occasionally used in a home-made brew of beer. Guavas grow in great abundance throughout Cuba on bushes and small-sized trees. The mamey Colorado grows on large trees, and is a fruit resembling a russet apple in colour and about the size and shape of an ostrich egg. The fig grows well in Cuba, the black green and Smyrna varieties all thrive, but, according to a recent report of the Cuban Ministry of Agriculture, no effort has been made to cultivate them since the retirement of the Spanish Government. Before that time the cultivation of this fruit was prohibited, except one tree which was allowed to each family. This was said to have been done to protect the home (Spanish) industry. The same laws also existed against the cultivation of grapes during the Spanish sovereignty. There are, however, old grape vines in Cuba which have never had any cultivation, but which are prolific bearers of excellent fruit, and thus show what an opportunity awaits those who will engage in the intelligent cultivation of the grape in Cuba. In connection with this it may be said that there is probably no country in the world which consumes so much wine *per capita* and produces less. Pineapples and oranges are grown in Cuba. As regards the latter, the fruit is very fine, and when the young groves now coming into bearing more fully develop, Cuba will make a strong bid for a high place in the fruit market of the world. Bananas grow to perfection, particularly in the eastern part of the island, where large banana plantations are under cultivation, more than 99 per cent. of the production going to the United States. In addition to the banana which is eaten as a fruit, there is another variety known as plaintain, which is used for cooking purposes. Green plaintains when cut thin and fried are much appreciated in Cuba, and are said to be far more nutritious than potatoes. They are also used in soups and stews, and are baked and prepared in many ways.

EMPIRE NOTES.

The Development of Nova Scotia.—No province of the North American continent surpasses Nova Scotia in the variety of its natural resources. The publicity which is being given to the Canadian West and Middle West and their wide development has diverted attention, somewhat, from the steady expansion of Nova Scotia. Numerous towns have sprung up even during the past few months, and many hitherto small townships are becoming prosperous manufacturing centres. Notably among the latter is New Waterford, in Cape Breton County. Near this township a large workable seam of coal was recently located, and five new collieries have been started. The population has been rapidly increasing, and the prospects suggest that New Waterford may eventually become the largest mining town in Eastern Canada. A considerable increase in trade at Louisburg has led to the suggestion being put forward that this town should be made the Canadian Fishguard. Fast trains could take passengers and mails from the steamers and run through to Montreal, Toronto, Boston, and New York, as well as to the Far West, at, it is said, a saving of many hours, and even days. According to recent returns, some 5,000 ocean liners have loaded and unloaded at the various wharves along the coast. These represent an aggregate tonnage of 5,000,000 tons. Then again there is the great inter-provincial trade, for which about 25,000 vessels are delivering 6,000,000 tons of freight annually. The Harbour Commissioners, though naturally elate at this success, do not intend to rest on their laurels, as it is estimated £500,000 will have been spent this year on increasing the shipping facilities. The railway system is also being extended to the Racine Pier, and another pier is being built in Market Basin. Additional facilities, too, are being provided at St. Helen's Island, and a number of new warehouses and reinforced-concrete freight-sheds are to be built, while the diversion of the St. Mary's current, by alteration of the McKay Pier, and preparations for the new dock are either in hand or shortly to be commenced. A large manganese deposit has been discovered at New Ross, Lunenburg County. The ore is reported to be

exceptionally free from iron. The vein is from 4 ins. to 48 ins. wide, and dips vertically. It is moreover stated that the ore is the very best grade known, and is suitable for use in glass works, varnish manufactories, and the making of dry batteries.

Financing Canadian Crops.—Under the Canadian Bank Act a measure of relief has been extended to Canadian banks, whereby, during the months of September, October, November, and December, an issue of notes equal to 15 per cent. of the combined capital and reserve can be made, in addition to their existing note issue. The reason for the adoption of this important step is said to be the ever-increasing call for banking accommodation, pending the movements of the crops, as during this period the fear of temporary money stringency is never absent. The additional circulation is to be covered, as is the normal note issue, by the collective guarantee of the banks. The emergency issue, however, is subject to a tax of 4 per cent. Since this tax absorbs practically the whole of the profits from the issue, there is no inducement to the banks to avail themselves of it, except as a temporary convenience, the provision for which is a further proof of the public-spirited policy of the Canadian Government.

A United States Delegation to Visit Australasia.—The question of closer commercial relationship between the United States and Australasia, as well as between Canada and Australasia, is evidently to the fore. Mr. Percy Hunter, of Sydney, New South Wales, has recently been touring through North America, with a view to securing the interest of American business men in the development of the Commonwealth. That his tour has been successful is proved by the fact that the Spokane Chamber of Commerce is organising a delegation to visit Australia and New Zealand to inquire into the economic and trade prospects of those countries. Representative business men are being invited from all the States of the Union to join the party, and it is anticipated that a hundred gentlemen will respond to the invitations. An interesting itinerary has been arranged, embracing Fiji, New Zealand, New South Wales, Queensland, Victoria, South Australia, Western Australia, and back *viâ* Auckland, New Zealand. In all, twenty-eight days will be spent in Australia, and the delegates intend to study, not only the openings for capital, but also the municipal politics of the cities and communities visited. The Spokane Chamber of Commerce expresses the hope that a deputation of Australasians will return the visit, and considers that a study of each other's business methods and a more intimate knowledge of each other's social development will prove of great benefit to these two important branches of the Anglo-Saxon race.

Public Works Programme for New Zealand.—Those interested in the public works policy of New Zealand will read with interest the important proposals submitted by the Hon. R. McKenzie, the Minister for Public Works. Speaking at Wakefield, N.Z., he said that £28,000,000 would be required—for the purpose of providing £18,000,000 for railway extension; £3,000,000 for public buildings and schools; £4,000,000 for road-making; £2,000,000 for harnessing water-power for the generation and distribution of electricity and for irrigation; and £1,000,000 for telegraphic extension and harbours. He laid stress on the advantages of hydro-electric force, and pointed out the necessity of keeping pace with the phenomenal growth of the Dominion in respect of railways, roads, telephones, and public buildings. He also outlined the policy of the Government in regard to financing these various undertakings, and pointed out three ways whereby it can be accomplished—viz., by means of loans, out of taxation, or by a fusion of loans and surpluses. The last method seems to be the one that is likely to be adopted, and he suggests that £1,500,000 a year shall be provided, by borrowing £1,000,000 and budgetting £500,000. He urged the necessity of undertaking and completing these works within a reasonable time, and pointed out that money borrowed and invested in reproductive works would earn its own interest.

Irrigation and Beet-Growing in Victoria.—In a recent issue, attention was directed to the forward policy of certain of the Australian State Governments in the matter of irrigation. This method of fertilisation has become essential in various parts of the island continent, and, in pursuance of the Government's land development and settlement proposals, a beginning has been made by the Victorian Water Commission, with one of the largest and most important irrigation schemes yet attempted in that State. It is proposed to construct a weir across the Murray River, near Kow Swamp, for the purpose of conserving, for irrigation purposes, many millions of gallons of water now flowing into the sea. Preliminary steps have been taken for carrying the scheme into effect, and the estimated cost is only £100,000. A great tract of the northern irrigation areas will benefit by the undertaking, as, when the weir is built, water will be carried, by gravitation, many miles through some of the most productive land in Victoria. In the matter of sugar-beet cultivation, Victoria has been attempting to establish this industry on a sound commercial basis for many years. Up to the present time, however, nothing of a substantial nature has been accomplished. In view of this, a report of the prospects in Gippsland, from the Director of Agriculture, is of some interest. The Director says that "A recent and thorough inspection of the Boisdale land suggests the likelihood that, as regards beet growing, the land will readily, under proper cultivation, yield twenty tons per acre of 'topped' beets, which will be paid for at the rate of £1 per ton delivered. Twenty-four tons to the acre were being delivered from Powerscourt, adjoining, on the day of my visit. Setting down the

cost of cultivation and freight even at the high rate of £10 per acre, a net return of £100 from the ten-acre plots may be expected, while the yearly purchase payments of the full blocks average less than £68. Assuming that only seventeen tons per acre is produced, then the net profit on the ten acres will be more than sufficient to pay the average annual purchase payments on the whole area of the block. The area not under beet each year should be devoted to dairying under intense culture, and the quality of the land for this purpose may be judged by the fact that some of the farms have been carrying a cow to one and a half acres, so that under good management from twenty to twenty-five cows can be kept on the balance of land costing nothing—purchase payments of the whole being returned by the beet crop each year. The project of the Government in assisting settlement on this estate for beet growing and dairying combined is therefore, I consider, the finest opportunity that has been yet offered in connection with the closer settlement movement. With the factory already established, the sugar market practically illimitable, and the dairy export trade constant, I cannot see how the project can fail if the right class of settler is secured." The factory referred to is located at Maffra, Gippsland, and had for a considerable time been idle. There appears now to be some reason to hope that a large and profitable sugar-beet industry will become established.

The French Explorers of Australia.—It is often forgotten that French explorers played a very large part in the discovery of various parts of Australia. In Western Australia and Tasmania, and also in New South Wales, there are names which indicate their French origin. Notable amongst these are Cape Naturaliste, Geographe Bay, and Cape D'Entrecasteaux, in Western Australia. The names of the first two were derived from the two French frigates that entered the splendid bay, on which the prosperous town of Busselton now stands, towards the latter end of the eighteenth century, and the Point D'Entrecasteaux was named after D'Entrecasteaux, who located various points in Tasmania. Cape Jervis in New South Wales was at first called the Fleurieu Peninsula, and the Council of the South Australian Geographical Society has recently decided to ask the Commonwealth Government to revert to its original French name, which it has borne on French maps since it was so named by Baudin's expedition. At the present moment Count Alphonse de Fleurieu, a member of the Paris Geographical Society, is in Tasmania, with the object of following the course of these early French pioneers. The Count states that he has gathered a good deal of information from various sources with regard to the early exploration of Tasmania, with which his great-uncle was closely connected as the organiser of expeditions. He is specially interested in the voyages of D'Entrecasteaux and Baudin.

NOTES ON BOOKS.

THE CRYSTAL PALACE, SYDENHAM. Messrs. Horne & Co. and Others.

This handsome folio, which purports only to be the auctioneers' catalogue for the sale of the Crystal Palace in November next, is really a very finely illustrated account of the origin and history of the Palace. There must be some fifty or more well-executed photogravures, reproduced from engravings, prints, and photographs, which have at various times been published in illustration of the Palace and its contents, the history of its erection in Hyde Park and transfer to Sydenham, and of various events in its career. Besides these illustrations there is a historical sketch tracing the history of the Crystal Palace from the time when the Great Exhibition of 1851 was first proposed down to the present date.

The account of the origin of the Exhibition is accurate, though naturally very brief. It would be easy to amplify it, and it is certainly an omission that no reference is made to the name of Sir Henry Cole, to whom, more than to anyone else, except perhaps the Prince Consort, is due the successful carrying out of the great scheme. There would never have been an exhibition if Prince Albert had not used his great influence in its favour, and it would never have been the success it was but for the energy and organising capacity of Mr. Henry Cole, C.B., as he then was. But the book does not purport to be a complete history of the Exhibition of 1851. What it purports to be is an illustrated account of the Crystal Palace and its contents, and in this aim it has succeeded extremely well.

GENERAL NOTES.

AGRICULTURAL INSTRUCTION DURING WINTER IN FRANCE.—The opening of classes during the winter months, for instruction in agriculture, has given good results. Until quite recently, little had been done in France towards following the example set by other nations in Europe, where winter schools have been in existence for many years past. In Germany there are no fewer than one hundred and eighteen of these schools, which are frequented by the sons of small proprietors and farmers, who could not spare them from home during the busy times of haymaking, harvest, vintage, etc. Austria has sixty-seven, and in Holland there are six. In France, however, little was done in this direction until 1900, when M. Léon Dabat, then a sub-inspector of agriculture, in a report to the International Jury of the Paris Exhibition, pointed out the necessity of such instruction. The first school of this kind was opened in 1902 at Langres, where the existing college buildings and teaching staff are utilised. This example was followed at Troyes, where there

is another winter school, aided by subsidies from the various societies of Agriculture, Horticulture, Viticulture and Forestry of the Department of Aube. These were followed by Lons-le-Saulnier in 1907, and Chartres in 1908; a winter course of practical agriculture will be opened this year at the Lycée of Chaumont, and another on viticulture at the College of Épernay, in the heart of the wine-growing district; other schools will be eventually established throughout the country. The course of instruction at these schools covers a period of two years. Each school is under the direction of a professor of agriculture, who gives instruction in that subject, as well as in viticulture or forestry. For the remainder of the curriculum he is assisted by the local professors; this includes geometry, land-surveying, drawing, physics and chemistry. Instruction in veterinary science and hygiene is given by a local veterinary surgeon, whilst lessons in first aid and domestic hygiene are occasionally given by one of the doctors attached to the hospital of the town.

Imports of Grapes to Germany.—According to a recent report from Berlin, the importation of grapes for wine-making into Germany has increased considerably during the last four years, as is shown by the following statistics. These figures do not include table grapes, of which large quantities are sent from Italy, and are given in metric quintals.*

Country.	1907.	1908.	1909.	1910.
Italy	41,260	66,740	66,440	172,097
Spain	105,927	72,313	70,140	119,183
Austria-Hungary	29,227	36,301	22,622	79,254
France	212,688	193,862	158,399	55,945
Greece	—	—	6,978	5,801
Other Countries	10,764	7,764	7,882	45,719
Quintals	399,866	376,980	332,461	477,999

This great falling off in the quantity of grapes imported from France is due to the increase of price in 1910 as compared with that of previous years. On the other hand, the wine-makers of the Rhine provinces, Würtemburg, and of Alsace-Lorraine, have made up the deficiency by purchasing grapes at cheaper rates in Italy, from the vineyards of Romagna, Modena and Mantua. In this way Italy has risen from the third place which she held before to become the chief source of supply.

French Trade with Algeria. — Algeria is undergoing a period of exceptional prosperity at the present time. The total value of the exports and the imports between that country and France has increased from 632,700,000 francs (£25,268,000) in 1909 to 825,334,000 francs (£33,013,360) in 1910, showing an increase of 193,634,000 francs (£7,765,360) in favour of last year. The exports from Algeria to France, which in 1909 amounted in value to 271 million francs (£10,840,000), in 1910 increased to 360 million francs (£15,600,000). This increase of 119 million francs (£4,760,000) may, to a great extent, be attributed to the bad harvest that year in France, causing her to draw upon the resources of the colony to make up for the deficiency. The following shows the quantities of some of the principal products of Algeria exported to France in 1910, as compared with those of 1909:—

	1909.	1910.
Grain	234,480 tons.	340,200 tons.
Wine	6,047,000 hectolitres (132,994,000 gallons)	6,693,174 hectolitres (147,249,828 gallons).
Olive Oil	15,000 quintals (about 30,000 cwts.)	79,000 quintals (about 158,000 cwts.)
Vegetables	18,408 tons.	23,400 tons.

The value of land in the colony has considerably increased during the last few years. Wine-growers in this more favoured climate are reaping a benefit from higher prices, due to the deficiency of the grape crop last year. The Bureau de Renseignements, established by the Algerian Government, is found to render good service to colonial farmers in pointing out markets in France for their produce.

The Imports of Motor-cars to Norway.—The imports of motor-cars by Norway during 1909 show a considerable increase in value as compared with those of the previous year. This is especially noticeable with regard to cars of French make. There has been, however, no falling off in the value of cars imported from other countries, as is shown by the following:—

Value of Motor Cars imported.

	1908. *Crowns.	1908. £ sterling.		1909. Crowns.	1909. £ sterling.
Germany	135,800	7,356	..	186,000	10,075
Great Britain	137,700	7,459	..	176,700	9,571
France	27,000	1,462	..	117,100	6,343
United States	10,800	585	..	56,300	3,050

Norway also promises to become a good customer for machinery for motor-boats. The motor is steadily taking the place of the sail in the extensive fishing fleet of that country. Although the manufacture of these motors is carried on successfully in Norway, the value of those imported from other countries during 1909 amounted to 1,557,100 crowns (£84,343). France only figured in this amount to the value of 1,700 crowns (£92).

Sericiculture in Hungary.—Sericiculture is an industry which has made considerable headway in Hungary during the last thirty years. In 1879 only 2,507 kilograms (5,528 lbs.) of cocoons, representing a profit of 7,400 crowns† (£308 sterling), were produced. Last year the production of cocoons had increased to 1,644,972 kilograms (3,627,163 lbs.), giving employment to 90,064 families, and realising a profit of 5,179,382 crowns (£215,808).

* Metric quintal = 220½ English pounds.

* Norwegian crown = 1s 1d. † 24 crowns = £1 sterling.

CANTOR LECTURES.

ROCK CRYSTAL: ITS STRUCTURE AND USES.

By Alfred E. H. Tutton, M.A., D.Sc., F.R.S.

Lecture I.—Delivered May 1st, 1911.

Rock crystal, quartz, the common crystallised form of silica, dioxide of silicon, SiO_2, is, from many points of view, the most interesting of all minerals, and forms the most instructive example of crystalline structure known to us, displaying the physical properties of organised solids, crystals, in a uniquely complete and perfect manner. From the fact of its ubiquitous presence the world over—silica being, after water, the oxide most largely developed in the accessible part of the earth—rock crystal was the first crystallised mineral to attract the attention of the ancient philosophers. Indeed, this mineral actually gave its name to the whole science of the crystal—"crystallography," for the word "crystal" is the anglicised Greek word for ice, κρύσταλλος, the ancients having believed that rock crystal was a form of ice produced by the severe cold of the higher regions of the Alps. It is especially interesting that Pliny should have left us the following passage of remarkable insight regarding rock crystal, in Book xxxvii. 9 of his "Natural History": *Quare sexangulis nascatur lateribus non facile ratio inveniri potest; eo magis quod neque mucronis eadem species est, et ita absolutus est laterum lævor, ut nulla id arte possit æquari.* Pliny had thus obviously remarked the hexagonal prismatic form of the crystals, and found it difficult to account for such regularity of form, and particularly for the varied appearance of the pyramidally-pointed ends; he also noticed the wonderful polish of the prism faces, which he considered to be such as no man could equal.

The popular belief, in the Middle Ages, that rock crystal was a harder form of ice is very plainly stated by Albertus Magnus about the year 1250; for he says that the high mountains make the ice so hard and dry that it becomes "crystal," *ex illo sicco coagulat glaciem in crystallum.* Even as late as 1550 Agricola was only able to report progress in the knowledge of rock crystal to the extent that it was not ice, but a denser product of cold, *succus frigore densatus.*

A very curious passage occurs in the writings of our own Sir John Mandeville of the year 1356, in which he states that "diamonds grow on rocks of crystal" in Indo-China, and that "they grow together, male and female, and are nourished by the dew of heaven. . . . If a man keep them with a little of the rock, and wet them with May-dew often, they shall grow every year, and the small will grow great." Thus we have here a remarkable record of the growth of crystals, and an early observation of the fact that precious stones and metals are often found associated with rock crystal, unless Sir John mistook the more perfectly-developed crystals of quartz for diamonds.

In the year 1669, a far-seeing treatise, *De solido intra solidum naturaliter contento*, was published by Nicolaus Steno, a Dane resident in Florence, in which the first real steps in crystallography were taken, all derived from the study of rock crystal. He showed that the prism was of truly hexagonal section, the angles being all 60°, and the terminations hexagonal pyramids, the apices of which in an ideally-formed crystal might be considered to be joined by the axis of the prism. He entirely rejected the idea of cold as the cause of the formation of rock crystal, and suggested a magnetic force of crystallisation. Being a great authority on anatomy, he pointed out that the growth of the crystal differed from that of living objects, which grow from within, in occurring by accretions from without, of minute particles of the

substance of which they are composed, carried in solution by a liquid. He showed further that growth occurred chiefly at the ends, as indicated by the transverse striæ on the prism faces, which he considered as growth marks. Moreover, he was the first to discover, or at any rate to record, the fundamentally important fact that the angles between the faces, that is, their mutual inclinations, were always the same, whatever the relative development of the faces might be.

This fact was further confirmed between the years 1688 and 1707 by Guglielmini, whose memoirs, moreover, relate also to other crystalline substances besides rock crystal, and the constancy of the angular magnitudes between the crystal faces of any one substance was extended by him into a great law of Nature. About this time also Huyghens—who had been studying the double refraction of Iceland spar, the wonderfully clear rhombohedral form of calcium carbonate, $CaCO_3$, which had then recently (1670) been discovered at Eskifjördhr, in Iceland, and its birefringence observed by Bartolinus—pointed out the further fact that rock crystal also possesses the property of double refraction, although to a much less extent than Iceland spar.

It will thus be seen what a large share the study of rock crystal has had in the pioneer work of unravelling the nature of crystals. If it should be desired to follow further the history of the development of crystallography, from the end of the seventeenth century to the present time, a concise account will be found in the lecturer's book on "Crystals" (Kegan Paul, International Scientific Series, 1911); and any who desire to undertake still deeper study and to carry out original investigation will find useful the lecturer's larger work, "Crystallography and Practical Crystal Measurement" (Macmillan, 1911).

After a few words about the origin and occurrence of quartz, we may pass on to inquire what is the modern conception of a crystal in general, and then to elucidate the particular inner structure of this wonderful mineral, quartz, to which it owes both its exterior shape and its physical properties.

That silicon dioxide, SiO_2, is the most abundant of all the naturally-occurring solid oxides is responsible for the very common occurrence of quartz in good crystals. For water, especially when it is slightly alkaline (with carbonates or hydrates of the alkalies) and warm, and still more when under pressure, is capable of dissolving quite appreciable quantities of silicon dioxide; in the case of the presence of free alkali, soda or potash, a soluble silicate of sodium or potassium may be formed, which, under certain circumstances (the reaction being a reversible one), in contact with carbonic acid derived by solution of atmospheric carbon dioxide in water, becomes decomposed to carbonate of the metal with liberation of free silicon dioxide. According to the circumstances, and especially as to whether the deposition is rapid or slow, the silica takes the form of opal or other amorphous variety of silicon dioxide, of clear crystals of quartz, or of agate or other semi-crystalline variety. The long periods of time during which slow processes are at work in Nature is doubtless the cause of the formation of the most perfect and beautiful crystals of the well-known minerals, and some such mode of formation is probably responsible for most of the development of quartz crystals in cracks and crevices of the earth's crust, so plentiful in mountainous districts.

Besides the deposition of quartz from the state of solution, however, volcanic action is responsible for the crystallisation of quartz from the fused rocks in deep-seated cavities; for the more acidic rocks (those containing the largest proportion of silica, a feeble acid, either combined in silicates or as free quartz), such as granites, quartz porphyries and rhyolites, contain innumerable crystals of free silicon dioxide, quartz, which are clearly revealed by their brilliant transparency when very thin slices of the rocks are cut, ground and polished for examination under the microscope, and particularly by the brilliant colours of Newton's first or second order spectra which are afforded when polarised light is used. We see this particularly well in the cases of the microscope slides of graphic granite, muscovite granite, and quartz porphyry exhibited on the screen with the aid of the projection polarising microscope. Here we have the case of the crystallisation of silicon dioxide from the molten state, in the midst of a magma itself more or less crystalline, exhibiting crystals of felspar and mica or hornblende, or a micro-crystalline (quartz porphyry) or crypto-crystalline (rhyolite) base in which the quartz crystals are very clearly marked, although their margins have often lost the hexagonal form owing to having been eaten into by the basal magma. Whatever be the mode of origin, however, the chief point to observe is that the internal structure of all perfectly-developed crystals of quartz is identical.

Indeed, the most wonderful thing about a

crystal, and one which is especially emphasised by quartz, is that whether it be of microscopic dimensions or of huge size, the structure is the same, and when the external parts are properly developed the faces are of the same character, inclined to each other at exactly the same angles.

Large crystals of quartz have been known from very early times, and were used even by the Romans as transparent material out of which to fashion "crystal" cups and vases, as will be more particularly referred to in the fourth lecture. Some very fine specimens of early carvings of ornamental vases of rock crystal are exhibited in the Waddesdon room of the Rothschild collection at the British Museum. The Alps have always proved fertile in cavities containing large crystals of quartz, one at Zinken, to which attention has recently been called by Mr. Cheshire, having been discovered early in the last century, with roof, walls, and floor lined with masses of magnificent large crystals, of which 50 tons were removed; the largest crystal weighed 800 lbs., and was placed in the Natural History Museum of Paris by the great Napoleon. More recently, in 1867, a cavity was discovered in a vein of smoky quartz from which 200 tons of crystals were removed, the largest weighing 250 lbs.

But the most remarkable find with which the lecturer is acquainted was that made in December, 1897, by Mr. J. E. Burton, at the old Green Mountain mine, Mokelumne Hill, Calaveras County, California. Particulars of this discovery the lecturer owes to the kindness of his friend, Mr. C. V. Boys, who is also a friend of the discoverer. Among a considerable number of large crystals, Mr. Burton eventually came across one, which was successfully removed after encountering many engineering and transport difficulties, which measured 11 ft. 7 ins. in circumference and 4 ft. 2 ins. in length, and the weight of which was just over 2,200 lbs., almost exactly a ton. It was of quite remarkable purity for so large a crystal, and was surrounded at the base by forty-seven smaller crystals which assisted in protecting it from injury, the weight of the whole mass being 2,630 lbs. It was secured by the well-known firm of Tiffany, of New York, for the cutting of crystal-gazing spheres, the largest being a sphere of 14 ins. diameter of clear crystal, besides several smaller ones of 8 ins. A sphere of rock crystal of 8 ins. diameter was already at that time in the possession of Miss Jay Gould, having been made in Japan from a large Japanese crystal of quartz. Indeed, the Japanese have long been known to be specially skilled in the cutting and polishing of rock crystal, and have been famous for the production of large spheres of rock crystal for "crystal-gazing" purposes, two of somewhat smaller size being shown on the table.

Passing now to the discussion of the question "What is a crystal?" we are in a position to state at once that the evidence is now overwhelmingly complete that a crystal is a homogeneous structure built up on the plan of a space-lattice, each of the unit cells of which is the habitat of a chemical molecule of the substance of which the crystal is composed, and of which it is the most highly organised solid form. Instead of regarding the centres of the cells, however, as the points representative of the structural units, we may equally well, by moving

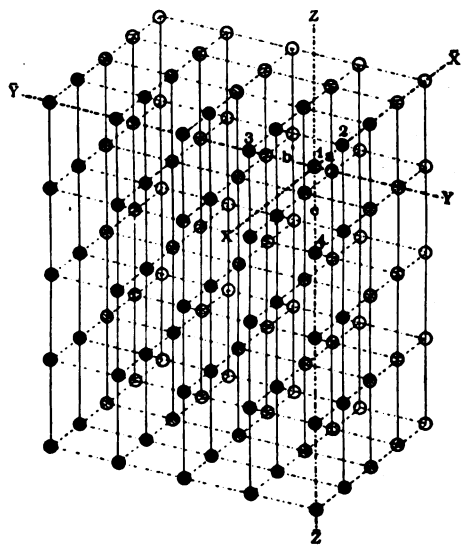

FIG. 1.—TRICLINIC SPACE-LATTICE.

them all equally parallel to themselves in imagination, consider the points or "nodes" of intersection of the three sets of parallel lines (the edges of the cells, the nodes being the corners of the cells) as the points representative of the chemical molecules. It was shown by Frankenheim and Bravais that there are fourteen such space-lattices possible, all of which show the full symmetry of one or other of the seven crystal systems, the cubic, trigonal, tetragonal, hexagonal, rhombic, monoclinic, or triclinic. As a typical example of a space-lattice, and the one of the most general form, the triclinic space-lattice is shown in Fig. 1.

But the chemical molecules, the arrangement of which thus determines the crystal system,

are not the ultimate units, being composed of elementary atoms, and it is the arrangement of these ultimate units, the elementary atoms, which determines the class of the system. For besides that class of each system which exhibits the maximum symmetry possible to the system, the so-called holohedral class, there are one or more (as many as seven in the cases of the trigonal and tetragonal classes) other classes possible which exhibit only partially, and in more than one way, the symmetry of the system, while conforming to the minimum symmetry essential to the system. Thus the cubic and hexagonal systems comprise each five classes, the rhombic and monoclinic each three, and the triclinic two classes, making with the fourteen already referred to belonging to the trigonal and tetragonal systems no less than thirty-two classes of crystal symmetry, each characterised by its own specific elements of symmetry.

The elements or criteria of symmetry are planes and axes of symmetry. A plane of symmetry is obviously a plane on each side of which the disposition of the parts of the crystal is similar, one half being the mirror-image of the other half, the plane of symmetry being regarded as the reflecting surface of the mirror. An axis of symmetry is such that rotation of the crystal around it for a definite aliquot part of a circle, which may be 180°, 120°, 90°, or 60°, brings the crystal to look precisely as it did before the rotation. The four kinds of axes of symmetry corresponding to rotations of the four amounts just specified are termed digonal, trigonal, tetragonal, and hexagonal axes, as two, three, four, and six such rotations respectively bring the crystal into the identical position started with.

Now the possession of a single hexagonal, tetragonal, or trigonal axis of symmetry is the characteristic of the three respective systems named after these specific axes, and quartz belongs to the third of these systems, the trigonal. Digonal axes, one or more according to the system, are common to all the seven crystal systems except the triclinic, which latter is either entirely unsymmetrical or in its holohedral class is symmetrical to the centre, that is, a holohedral triclinic crystal is composed of pairs of parallel faces. But the rhombic system is the one pre-eminently characterised by digonal axes of symmetry, there being three possible, identical in direction with the rectangular but unequal crystallographic axes of reference. The monoclinic system possesses one such digonal axis, which is perpendicular to the unique plane of symmetry possessed by the crystal. The system of highest symmetry, however, is extremely rich both in planes and axes of symmetry, its supreme holohedral class possessing no fewer than nine planes and thirteen axes of symmetry, of which six are digonal, four trigonal, and three tetragonal axes. Thus a holohedral cubic crystal, such as a garnet for instance, is endowed with no less than twenty-two elements of symmetry.

Symmetry axes must not be confused with the crystal axes of reference. These latter are three in number in all the systems but the hexagonal, in which four are employed, three being horizontal ones inclined at 60° to each other, while the fourth, identical in direction with the hexagonal axis of symmetry and usually arranged vertically, is perpendicular to the three just referred to. These axes are parallel to the edges of the hexagonal prism terminated by a pair of flat normal end-faces, the so-called basal-plane faces. In the cubic, tetragonal, and rhombic systems the crystallographic axes intersect rectangularly and are parallel to the edges of the cube, the tetragonal prism, and the rectangular rhombic solid formed by the primary faces (pinakoids) of the rhombic system analogous to those of the cube; the three axes are of equal length in the case of the cube, and are identical in direction with the tetragonal axes of symmetry; two are equal in the case of the tetragonal axes, the third axis of different length being identical in direction with the tetragonal axis of symmetry; while in the rhombic system all three axes are unequal. In the monoclinic system the three unequal axes are like the rhombic ones, except that one of them is inclined to the plane of the other two, and in the triclinic system all three are inclined to each other as well as being of unequal lengths. In the trigonal system the three crystal axes are parallel to the edges of the primary form, the rhombohedron, which may be regarded as a cube standing on one corner with a diagonal vertical, the cube being either compressed or extended along this diagonal direction, which is identical in direction with the singular trigonal axis of symmetry. It is also possible to use the hexagonal axes for the description of trigonal forms, and indeed, under the old methods of description, before the present truly scientific method of regarding axes and planes of symmetry as the only real criteria of symmetry, the trigonal classes were considered as "hemihedral" classes of the hexagonal system, that

is, hexagonal forms in which half the number of faces constituting the hexagonal classes were suppressed.

Now quartz crystallises, as already mentioned, in this particularly interesting trigonal system of symmetry. The holohedral class of the system, exhibiting the maximum degree of symmetry, possesses, in addition to the essential vertical axis of trigonal symmetry, three symmetry planes mutually inclined at 120° and intersecting in the trigonal axis, as well as an equatorial plane of symmetry horizontally arranged at right angles to the trigonal axis, and also three digonal axes of symmetry lying in the equatorial plane at its intersection with the three vertical symmetry planes. But quartz does not develop this full holohedral trigonal symmetry, but that of the trapezohedral class of the system, no plane of symmetry being present, and the three digonal axes occupying positions in the horizontal plane midway between those of the holohedral class. We may represent these elements of symmetry by the diagrams given for right- and left-handed quartz respectively in Figs. 2 and 3.

The trigonal axis perpendicular to the plane of the paper (the equatorial plane) is represented diagrammatically by the little equilateral triangle in the centre, the three digonal axes by the dotted diameters terminated by little ellipses, an equilateral triangle and an ellipse

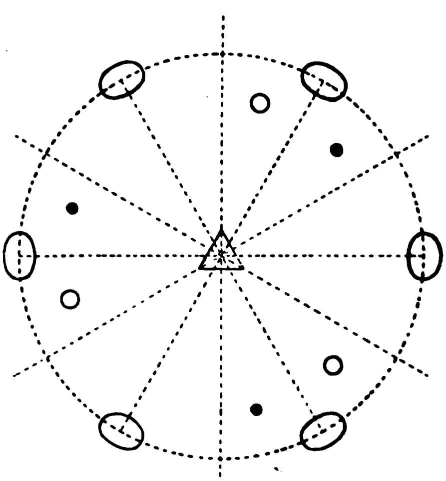

Fig. 2.—Elements of Symmetry of Right-handed Quartz.

being the symbols introduced by Gadolin for the ready indication of a trigonal and a digonal axis of symmetry respectively. And this leads us to the consideration of a most convenient mode of drawing a plan of the crystal faces. For we may imagine each of the diagrams in Figs. 2 and 3 to be the projection of a sphere on its equatorial plane, the eye being supposed to

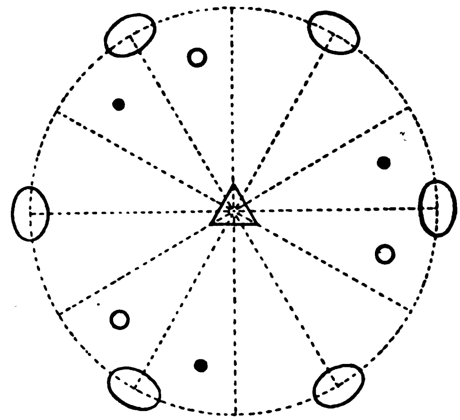

Fig. 3.—Complementary Figure for Left-handed Quartz.

be situated at the pole; and we may then adopt the exceedingly useful convention of employing such a spherical, or more correctly stereographic, projection as our plan displaying the distribution of the faces and the symmetry of the crystal in an obvious and interesting manner. We imagine the crystal to be placed at the centre of the sphere, and that normals are drawn to all the faces or their planes produced, from the centre of the sphere, and the points where these normals cut the surface of the sphere are considered as points or "facial poles" representative of the faces. If, then, we take the solid dot near the front of Fig. 2 and to the right of the back-to-front diameter as such a facial pole of a face of most general character, inclined to both the vertical trigonal axis and to the horizontal digonal axes, then it will be obvious that the operation of the trigonal axis, rotation for 120°, will require two other facial poles to be present, similarly placed with respect to the three digonal axes and at 120° from each other in the diagram. Also the operation of each of the digonal axes, rotation for 180°, will require the presence of a second facial pole, represented by a little ring instead of a dot, at an equal distance on the other side of that axis, and representing a face in the lower hemisphere. Now these six faces thus required to be present by the symmetry elements in operation, when one such face is given as present, make up a double trigonal pyramid of which the lower half is rotated somewhat with respect to the upper, screw-wise, and the solid thus produced is

known as a trigonal trapezohedron. The one corresponding to Fig. 2 is represented in Fig. 4.

But there is no more reason why we should have started with a dot-pole to the right of the

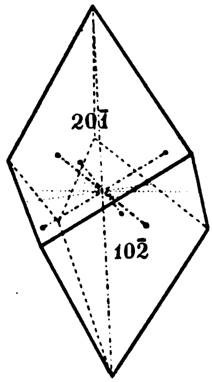

FIG. 4.—RIGHT TRIGONAL TRAPEZOHEDRON.

back-to-front diameter of Fig. 2 than with one to the left of the latter, and the similar diagram drawn on that assumption is shown in Fig. 3, and the solid which it represents, complementary to that shown in Fig. 4, is given in Fig. 5. Now it will be at once apparent that Figs. 2 and 3, and also Figs. 4 and 5, are the mirror-images or reflection-complements of each other. This means in actual fact that two trigonal trapezohedra, which are the mirror-images of each other, are possible, and the two solids are quite distinct, for no amount of rotation will bring either to resemble the other. That of Fig. 4 is called the right trigonal trapezohedron, and that of Fig. 5 the left variety. This fundamental fact

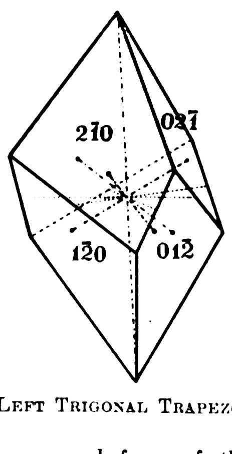

FIG. 5.—LEFT TRIGONAL TRAPEZOHEDRON.

respecting the general form of this class of trigonal symmetry affords the explanation of the two varieties, right and left-handed, of quartz, which mineral shows characteristic development, in the well-known little x faces, of the two trapezohedra. Indeed, so fundamental is the fact that this class of trigonal symmetry is currently known both as the trapezohedral class and the quartz class.

Two characteristic crystals of quartz, a left-handed and a right-handed one, are shown in Figs. 6 and 7, on which the small faces x are those of the left and right trigonal trapezohedra respectively. Also, the little adjoining faces s are those of another pair of mirror-image complementary and quite distinct forms of the trapezohedral class of trigonal symmetry, the left and right trigonal bipyramids. The other faces shown on Figs. 6 and 7 are those of the hexagonal prism m, which is a form common to both the hexagonal and trigonal systems, and which is also common to both varieties of crystals of the trigonal trapezohedral class; also those of the two complementary rhombohedra r and r', which together make up what appears

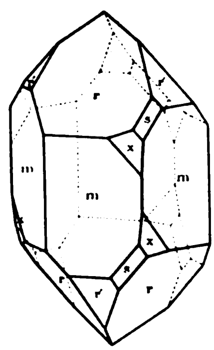

FIG. 6.—RIGHT-HANDED QUARTZ.

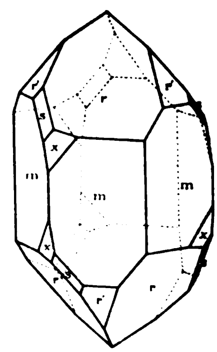

FIG. 7.—LEFT-HANDED QUARTZ.

to be the hexagonal pyramid terminating each end of a fully-developed quartz crystal. Alternate faces of the pyramid belong, however, to different rhombohedra, three to r and three to r', and they are often characteristically different, either in amount of development, or in polish, the faces of the rhombohedron r being much more brilliant than those of r'. Moreover, the quartz crystals from a particular locality in Ireland characteristically show one rhombohedron only, without a trace of the other.

It will be observed, further, that the little s and x faces occur replacing left solid angles on a left-handed crystal, and right solid angles on a right-handed crystal. Also, if x faces be absent, a good little s face is often present, and it is usually marked by striæ parallel to the edge sr, which enable the location of the face, and its nature, to be recognised.

THE INTERNATIONAL ELECTROTECHNICAL COMMISSION.

REPORT OF THE FOURTH MEETING, HELD IN TURIN FROM SEPTEMBER 7TH-11TH, 1911.

The fourth meeting of the International Electrotechnical Commission was held in Turin last month, coming to a close on September 11th.

The work of the Commission has steadily grown in importance during the last few years, and the meeting that has just terminated was considered one of the most successful yet held. The need for such a supreme international authority on electrical matters had made itself evident. The relations between engineers and firms concerned with electrical goods in different countries make it essential that there should be some common understanding regarding the rating of machinery and terms and symbols used. The Commission has already been signally successful in rendering assistance in this direction, and year by year has gained additional support. At the last meeting no less than twenty-one different countries were represented, and this led one of those present to refer to the gathering as "The World's Future Electrotechnical Parliament."

The opening ceremony and subsequent meeting took place in the Palazzo della Prefettura, where an impressive address of welcome on behalf of the Italian Government was delivered by His Excellency the Minister of Posts and Telegraphs, Signor Avv. T. Calissano. The proceedings were formally opened by Colonel R. E. Crompton; and Professor Elihu Thomson, the honorary President, who had travelled specially from Boston to attend this meeting, delivered a most interesting and inspiring address.

"To us members of the Electrotechnical Commission," he said, "gathered together under the canopy of the glorious Italian sky, historical memories are bound to occur. When the people of the Orient, reduced to impotence by their overwhelming riches, allowed the world's sceptre to slip from their enfeebled grasp, it was here in Rome that it was again raised aloft. The civilisation of the Latin races developed to so high a degree, that even to-day the most advanced nations are glad to take advantage of it. And when, in its turn, the great Roman Empire fell before the hoards of Barbary, when intestine wars and medieval invasions decimating Italy seemed once more to arrest the march of civilisation, the torch of the Latin races, far from being quenched, burst anew into brilliant flame. Such names as St. Thomas Aquinas, Dante, Michael Angelo, Galileo, and Leonardi da Vinci, witness the fact that in Art, as in Science and Philosophy, Italian genius has been able to produce men before whom the centuries to come will pay homage even to the end of time.

"Coming now to the field of science which is the real reason for our assembling here to-day, we remember those pioneers Galvani and Volta, to whose genius and ability the first practical development of electrotechnics is due. Fifty years later Antonio Pacinotti gave us the principle of the dynamo electric machine for continuous currents. Later Galileo Ferraris discovered and gave to science the revolving field, which has enabled polyphase currents to be made use of with such success."

Proceeding, Professor Thomson alluded to the development of wireless telegraphy, with which the name of Signor Marconi will always be associated. It was befitting, he said, that, at this celebration of fifty years of national unity, Italy should hold an international exhibition, which would serve as a centre for several congresses and illustrate both the advances in electrical science and its influence on the commercial development and prosperity of nations.

Professor Thomson also dwelt upon the fact that much of the work so far carried out had served to pave the way for future efforts. It was necessary to proceed with caution, because conditions of the electrical industry were constantly changing, and it was not desired to retard the progress by trying to standardise matters which were in a constant state of change. The Commission, however, was alive to the importance of conducting its work in such a way as to avoid anything of this nature, and to be of permanent assistance to the electrical industry.

The variety of subjects which the Commission had to deal with was very great, and it was therefore desirable that similar international committees should be appointed to report to the central office on their respective subjects. This suggestion afterwards received the approval of the Congress, and three sectional committees of this kind have been formed.

One subject on which there was a special need for agreement was the nomenclature and terms used in illuminating engineering. It was common knowledge that the expressions of methods in different countries differed considerably,

and it would be advisable for the Electrotechnical Committee to co-operate with the illuminating engineering societies in Europe and America when dealing with these points. In passing, he welcomed, on behalf of the Commission, the presence of Mr. Leon Gaster, the hon. Secretary of the Illuminating Engineering Society of London, who had been specially invited to attend this gathering, and laid stress on the important international organisation of the society which he represented.

Colonel R. E. Crompton, hon. Secretary of the Commission, gave a brief description of the work undertaken since its formation less than four years ago. He recalled that in 1908 there were only ten countries participating, whereas local electrotechnical committees in no less than wenty-one countries have now been appointed, and several other countries have since undertaken to do so. He also pointed out that the short biography of the life and work of their late President Mascart, so ably compiled by Professor Paul, had been very much appreciated, and suggested that the masterly brief biography of the late Lord Kelvin, written by Professor Silvanus Thompson, should be published in English and French at the expense of the Commission. This suggestion was adopted unanimously, and we may look forward to seeing this valuable addition to the publications of the Commission in print very shortly.

The official meeting took place on Monday, September 11th, and a number of important resolutions were passed unanimously. Many of these had to deal with the list of terms previously submitted, which were now adopted unanimously after a few slight modifications had been made in consultation with local committees in different countries.

Perhaps the most important resolution was that proposed by Dr. Budde and seconded by Mr. Alexander Siemens, regarding the symbols to be used to represent current, electromotive orce, and resistance respectively. It is a common experience of students of electrical engineering that the text-books in different countries have followed different methods of denoting these quantities, and much confusion and needless inconvenience have been the result. It has now been agreed that the list shall be the same in all countries, namely: I for current, E for electromotive force, R for resistance. In order to arrive at this desired result, concessions were made by several nations. Germany, for example, abandoned the letter W (Widerstand), hitherto used for resistance, and Great Britain C, previously used to denote current. This simplification should prove of great convenience, and we may hope that it may be followed in other directions.

Another matter on which valuable agreement was arrived at, was in connection with the graphical representation of alternating electric and magnetic quantities, it being resolved that in future advance in phase should be represented in the counter clockwise direction. This again is an important decision to students, for text-books in different countries have hitherto sometimes followed exactly the reverse convention, so that the same diagram might occur in two books with opposite meanings.

Other resolutions referred to the rating of electrical machinery and apparatus, the propositions of the previous unofficial Congress in Brussels, 1910, being adopted without modifications.

The necessity for studying the terms and symbols used in connection with illumination was pointed out by the hon. Secretary of the Illuminating Engineering Society of London, Mr. L. Gaster, who suggested that the various national committees should be requested to put themselves in touch with the societies in their respective countries dealing with these questions. The proposal received the support of Dr. A. E. Kennelly and Dr. Clayton Sharp, speaking as President and Past President respectively of the Illuminating Engineering Society in the United States, and the Commission unanimously accepted the propositions, and passed a resolution to co-operate with the illuminating engineering societies on these matters in the future.

The resolutions of the International Electrotechnical Commission will doubtless go far to pave the way for agreement among electrical institutions, and it may be hoped that a similar co-operation on the part of the gas institutions will be secured.

The question of future meetings of the Commission also came up for discussion, and it was decided, on the proposal of Professor L. Lombardi, seconded by Mr. Alexander Siemens, that the next official meeting should be held in Berlin in 1913.

Mr. Gano Dunn, President of the American Institution of Electrical Engineers, then offered a cordial invitation of that Institution for the subsequent official meeting to be held at San Franciso in 1915, on the occasion of the opening of the Panama Canal. Professor Feldmann, seconded by Mr. W. Duddell, expressed

the thanks of the Commission to Mr. Dunn for this invitation and its willingness to hold the official meeting in San Franciso as suggested. It was also resolved to instruct the central office to assist the American Institution of Electrical Engineers in promoting an international Electrical Congress to take place simultaneously with a meeting of the Commission.

It may be added that a most important resolution was subsequently passed at the meeting of the International Electrical Congress, which took place in Turin last month. The fact that the meetings of the Commission and the Congress were held at the same time and at the same place proved to be exceedingly convenient, and it may be hoped that the great success of the gathering in Turin will form a valuable and encouraging precedent. It was decided that the time and place of meetings of Congresses in future should be determined by the International Electrotechnical Commission, the organisation of the details of the meeting being entrusted to the local committee working in co-operation with various institutions concerned.

This decision to place the organisation of future International Congresses under the supervision of the International Electrotechnical Commission, which is a supreme administrative authority in electrical matters, has received very general approval.

In conclusion, it only remains to be noted that the proceedings of the International Electrotechnical Commission were most cordial throughout, and it is pleasant to see that whatever political differences may divide nations, their men of science recognise no geographical or other artificial barriers, and are willing and able to meet together and make concessions for the common weal. The election of the new President, Dr. E. Budde (the present President of the Verband Deutscher Elektrotechniker), was proposed by Mr. R. V. Picou, the President of the French Electrotechnical Committee, and carried with acclamation.

It may be added that the fact of the meeting being held in Turin this year was due to the courtesy of the German delegates, and especially of Professor Dr. Budde, the newly-elected president, in waiving their prior claim for the gathering to take place in Berlin. In this Dr. Budde received the able assistance and support of the untiring secretary of the Verband Deutscher Elektrotechniker, Herr G. Dettmar, and the Commission was also honoured by the presence of Geh. Ober Postrat Prof. Dr. D. K. Strecker, President of the Symbols Committee of the Elektrotechnischer Verein.

Among the official delegates of the different countries who were present on this occasion may be mentioned: Mr. Alexander Siemens, Professor Silvanus P. Thompson, and Major W. A. J. O'Meara (Great Britain), Mr. Gano Dunn (President of the American Institution of Electrical Engineers), Mr. C. O. Mailloux (U.S.A.), Dr. E. Budde (Germany), Mr. F. H. Mears (Government of India), MM. P. Boucherot, R. V. Picou, and F. Laporte (France), E. Gerrard and O. de Bast (Belgium), Professor L. W. Gill (Canada), Professor A. Larsen (Denmark), Don Luis de la Pena (Spain), Professor C. Feldmann (Holland), M. de Chatelain (Russia), Professor J. Landry (Switzerland), Mr. C. A. Rossander (Sweden), Mr. A. Costello (Mexico), Dr. A. Oya (Japan), Mr. J. Muller (Ecuador), etc.

Special mention should be made of the valuable services of Professor Luigi Lombardi, the President of the Italian Institution of Electrical Engineers, who kindly presided over the unofficial meetings; of Professor G. Grassi, and of Signor Guido Semenza of the Italian Local Committee; and, finally, acknowledgment is due to Colonel R. E. Crompton, the hon. Secretary of the Commission and its indefatigable general secretary, Mr. C. le Maistre, on whose shoulders much of the work of bringing the meeting to a successful issue has fallen.

ESTABLISHING A SOLAR OBSERVATORY IN AUSTRALIA.*

The movement has gained ground steadily during the past year, and it is evident from the support it has received that much more widespread sympathy has been accorded to it than could have been anticipated at the outset. In Australia, where there exists a Solar Physics Committee to co-operate with the British Association Committee to promote the proposed solar observatory, the movement has been once more the subject of a favourable resolution by the Council of the Australasian Association for the Advancement of Science, and public attention has been recalled to the subject by the expedition of British astronomers that passed through Australia *en route* for the

* Report of the Committee, consisting of Sir David Gill (Chairman), Dr. W. G. Duffield (Secretary), Dr. W. J. S. Lockyer, Mr. F. McClean, and Professors A. Schuster and H. H. Turner, presented to the Section of Mathematical and Physical Science of the British Association at Portsmouth, 1911.

solar eclipse at Vavau, in particular by Dr. Lockyer, a member of this Committee.

In England the desirability of Australian co-operation in solar research has been emphasised in several ways. Speaking at the Royal Society of Arts, the Permanent Secretary of the Commonwealth Office described Australia's eagerness to share in those pursuits of science in which she is best fitted to participate, and referred to the action taken by Mr. Deakin's Cabinet in offering the annual upkeep of this observatory, provided that £10,000 were forthcoming from private sources for its equipment. The British Empire League has accorded the proposal its hearty sympathy, and is now vigorously assisting the project by an active appeal to its members and sympathisers to support the movement.

It seemed opportune to take advantage of Mr. Fisher's presence in London to advance the observatory scheme, and a deputation was formed to wait upon him. The Royal Astronomical Society appointed the Astronomer-Royal, Sir David Gill, and Professor Newell to attend this deputation, the British Empire League being represented by Lord Avebury, and this Committee by the Chairman and Secretary. In the unavoidable absence of the Prime Minister of the Commonwealth at an extraordinary meeting of the Imperial Conference, the deputation was received by Mr. Batchelor, the Minister of External Affairs of the Commonwealth.

Sir David Gill, leading the deputation, referred to the gap in longitude which it is necessary to fill before the complete scheme of solar research can be effected, a gap which an Australian solar observatory would obviate, and pointed out her unique position south of the Equator. He mentioned the fact that the British Association had voted the sum of £50 towards the scheme, and asked on behalf of the Committee that the Australian Government would relieve him of the responsibility of this money by promoting the object for which it had been voted. He trusted that the work done by existing State observatories would not be interfered with by the establishment of a new observatory for the study of the sun.

The Astronomer-Royal referred to the excellent climatic conditions of Australia for solar observations. He pointed out the great theoretical value of a close study of the sun in its relation to the study of the physical conditions of the stars and of their development. He emphasised the importance of research work being carried on, because of its educational value, and expressed the view that the existence of a solar observatory would stimulate the study of physics generally as well as astrophysics in the universities of Australia.

Lord Avebury dwelt upon the unusual support that had been accorded to this scheme by learned societies, and suggested that such an observatory if established would ensure three of the four links in the chain of solar stations round the earth being within the British Empire, and all four—the British, Indian, Australian, and American—being conducted by English-speaking peoples.

Dr. Duffield referred to the progress of the movement in Australia, to the previous action of the Fisher Ministry in offering £1 for £1, to the vigorously supported public meeting in Melbourne, and to Mr. Deakin's promise of the upkeep provided £10,000 were privately subscribed. He further stated that over £4,000 had already been offered in money and apparatus, and that this was a sufficiently substantial sum to convince the Government that the people of Australia are in earnest in the matter. The press of Australia were unanimous in its favour.

The Minister, in reply, stated that he was impressed with the desirability of filling the gap in longitude, but that before action could be taken it would be necessary to consult the other members of the Cabinet. This would be done upon his return to Australia, and he personally promised to urge upon the Prime Minister and his colleagues the desirability of establishing a solar observatory in Australia.

THE ORIGIN AND PRODUCTION OF CORRUGATION OF TRAMWAY RAILS.*

The explanation of the presentation of this paper on a subject previously discussed in a brief paper by the author before the Association in 1907 is the fact that, although the serious increase of corrugation since that date has caused much trouble, expense, and public annoyance, the real cause of corrugation has not been recognised. One and the chief reason for this is the fact that corrugation can only be prevented by calling a halt in the direction in which tram-car design has increasingly tended in recent times. Great weight on small wheels at high speeds means a combination which is destructive to any permanent-way which, as a tramway or street railway, can be made with any known materials and used on the common highway. As an abstract of the paper which the author now offers, he cannot better present the salient points appealed to in his explanation of the causes and production of corrugation than by repeating them in the form previously outlined, and this he does with a full knowledge of the numerous writings and experiments on the subject and of inquiries by home and Continental bodies troubled by this engineering ailment.

Although the physical and mechanical conditions involved in the origin of corrugation are complex, the mode of operation of the causes is simple, and for an explanation simple phenomena of known recurrence and adaption in engineering works

* Abstract of a paper read by Mr. W. Worby Beaumont, M.Inst.C.E., before the Engineering Section of the British Association at Portsmouth, 1911.

may be appealed to. When a piece of cold iron or steel is subjected to pressure exceeding the limit of elastic compression by a rolling or hammering action, or by these combined, the result is spreading of the material and change of the dimensions. The hammering or rolling work done upon a surface tends to compress the material beneath it; but being nearly incompressible and unchangeable in density, the material flows, and change of form results.

Generally the material thus changed in form suffers permanently no greater stresses than those within its elastic limit of compression or extension. When, however, the material is not free to flow or change its form in the direction in which the stresses set up would act, the effect of continued work done on the surface is the growth of compressive stress exceeding elastic resistance.

In railway rails the freedom for the flow of the material is limited. Hardening of the surface takes place, and destructive compression of the surface material is set up. If the material be cast-iron the destructive compression causes crumbling of the superficies, and the consequent relief of the material immediately below from stress beyond that of elastic compression; but when the material is that of steel rails, crumbling is delayed by its greater elastic extensibility and toughness, the upper part near the surface being under intense compression, differentiating from a maximum at the surface.

The repeated running of the heavily laden tram-car wheel over the rail does thus gradually compress the surface of the crown of the rail. Of this stress transversely the material relieves itself partially by the detrusion at the edges of the rail, where it forms a lip on the outside or on the groove side, or on both. This lip remains on the outside of the rail, but is worn off on the inside by the wheel flange. In the longitudinal direction the stresses arising from the compression of the surface material are not thus relieved. The heavily laden tram-car wheel presses into the surface of the rail, and as it rolls along presses before it a wave of compression the translation of which involves the destructive rupture of the surface or the rise of the wheel over the minute crest of the wave. The result is the formation of an extremely hard surface in patches of various shapes and lengths, and separated by distances depending on several conditions, including the mechanical properties of the rail, its combined hardness and toughness. Where the bright hard patches alternate with an approach to regularity with the dull and rougher surface patches the result is known as corrugation. This character of surface may be found on every heavily worked tramway under conditions of such impartial contrariety that it may be ascribed to conditions of origin which are general.

The remedy appears to be: (1) Lighter cars; (2) larger wheels; (3) harder rails; (4) moderate speeds.

HOME INDUSTRIES.

Strikes and Wages.—It was remarked in these Notes a week or two ago that, although a strike may bring apparent advantage to the strikers—as in the recent disturbances at Cardiff—the victory may really spell loss to the winners, and the remark was illustrated by owners having largely ceased to sign on crews at Cardiff. This apparent gain but real loss is shown in another way by the action of a shipping company noted for its liberal treatment of its employees. As a result of the recent strikes, says *Fair Play*, this company gave an advance in wages ranging from 1*s.* to 3*s.* per day, while the seamen and firemen also secured large increases. Previously the company had always behaved very generously towards their men, and when the ships were in port, instead of discharging the seamen and firemen, found work for them and kept them on at day wages. Under the new arrangement they decided to have done with the men at the end of each voyage and to re-engage them when required, which would be just prior to the sailing of the vessels. They also employed in the different gangs for coaling, etc., more men than were necessary. Now the whole question of the employment of these men has been reconsidered, and only sufficient men are being taken on to do the work. And this is what is being very generally done. The employers consent, under pressure, to pay higher wages, but it is a grudging consent which leads them to overhaul expenditure in every direction, and to discard every consideration but that of legal liability, a change in the relations of masters and men that can hardly fail to deepen existing ill-feeling and industrial unrest.

The Minimum Wage.—There is grave reason to fear that the present acute unrest in the mining industry may spread from Wales to other parts of the country within the next few weeks, to the enormous loss of all directly concerned, that is to say, to a very much larger portion of the community than is generally supposed. Speaking at the annual meeting of the Bromhill Collieries last week, Lord Furness intimated that if the three-shift system is abolished the company will be unable to work its collieries, and they will be closed at once. The substitution at these collieries of two for three shifts would, if the managers' estimate is correct, entail a loss of from £30,000 to £40,000 per annum. Then, as to a minimum wage, the demand is for 2½ per cent. beyond present figures. This, as Lord Furness contends, cannot be paid unless the selling price is advanced. They pay an average of 7*s.* 5·85*d.* per day for every hewer, without taking into account the value of free rent and free fuel. If no man is to receive less than 7*s.*, and as much more as a good working place can give him, the hewing costs must increase largely, and the county average would probably reach 10*s.* for a day of seven hours. The result would be that prices in the home trade must rise accordingly, and the

export trade would be diminished. Meantime, the conference to consider the question of payment to coal-hewers for work done in abnormal places, which affects all the coal-mining districts in the Kingdom—though the trouble is much more acute in some districts than in others—has met and separated without coming to an agreement. The coalowners admit the principle of payment in abnormal places commensurate for the work done, but suggest that the matter is one for local settlement. The men call for a national settlement on the basis of the recognised minimum or average wage of the district, the setting up of machinery for the determination of all disputes as to abnormal places, and the payment of the average wage pending the settlement of the dispute. The difference between the proposals seems so small that one wonders at the failure to come to an agreement, and it is surely not too much to hope that a rupture will be avoided. Unfortunately a section of the men seem bent upon it.

Steamers and Boats.—The mishap to the "Olympic" has directed attention anew to the question of the adequacy of the boats on passenger ships and the machinery used to put them into the water. The launching of boats from a steamer so high out of the water as the "Olympic" is a difficult operation. As a rule, comparatively few deck hands are carried, and probably the "Olympic" has not more than sufficient to launch, say, four or five boats at a time. This points to the necessity for having boat-lowering gear that can not only be quickly worked but that can be worked by a small number of men. When a steamer is damaged by collision, and makes water, she naturally lists over on the side that is damaged, and if the list is at all heavy it makes it difficult, and sometimes impossible, for the boats to be swung out on the opposite side. It is, therefore, important that they should be swung out promptly before a serious list has developed. This truth has been recognised and acted upon by the South-Eastern and Chatham Railway Company on their boats running between England and France. The davits are those of Captain Petts, and are so constructed that by simply turning a handle fitted to the davit (and this could be done by the smallest of the steward's boys) a boat can be swung out ready for lowering in less than a minute no matter what angle the steamer is lying at. The davit is simple and always ready for use, and it is a little surprising, and indeed disconcerting, that other Channel steamers are allowed to carry large numbers of passengers although provided only with davits that are almost unworkable, and with boat-lowering gear quite unequal to the requirements of emergency.

Iron Ore from Russia.—It is understood that the Russian Government have it in contemplation to prohibit the exportation of iron ore by sea. For some time past its exportation over the western frontier has been prohibited. England, Germany, and Austria are the principal consumers, so that the measure is of interest to this country. The bill, if passed, will chiefly affect the Kriowoi-Roger and Donetz districts, the exports from which pass almost entirely through the port of Nicolaieff. They have been steadily increasing for some years past; exports of iron ore from the Donetz basin amounted to 26·7 million poods for the first five months of 1911, against 24 million poods for the corresponding period last year, and the Russian iron manufacturers during the same period took 97·8 million poods, against 84·5 million poods. It is estimated that the Kriowoi-Roger deposits of iron ore, which occur chiefly on the borders of the Ekaterinoslav and Cherson Governments, amount to about 5,250 million poods, representing 3,250 million poods of iron, whilst the total iron ore deposits in the country are about 50,000 million poods. The present export of iron ore from Russia would have to be very largely increased before it could have any very appreciable effect upon the ore deposits of the country.

A New Bleaching Process.—A new bleaching process has just been patented in Germany which dispenses with the use of ordinary bleaching powder solutions. The rights have been purchased by a new company, the Air Bleaching Company, Eilenburg, Germany, who will grant licences to those wishing to adopt it. The capital of the undertaking, the Luftbleiche, G.m.b.H., is 100,000 marks. The cloth is packed in the kier, which is specially arranged so that the goods are completely covered with the alkaline solution during the whole operation, a small quantity of manganese sulphate being added to the ordinary caustic soda solution. The goods are boiled about a couple of hours without the admission of air, and then a stream of air is forced into the kier under a pressure of about 3½ atmospheres, or 1½ atmospheres above the steam pressure. It is said that after further boiling twelve hours, air being forced into the kier during the whole time, the goods are completely bleached, no subsequent "chemicking" being necessary. A considerable saving in time and drugs is claimed.

Aluminium.—Aluminium prices have now fallen to a point at which manufacturers cannot sell at a profit. The explanation is, of course, over-production, and as the attempts to form an aluminium syndicate have been abandoned it is not likely that there will be much improvement for some time. At the beginning of the year the price to German consumers was about £70 per ton, during the past month it has been considerably under £60, and large quantities are said to be obtainable at about £52 per ton. Prices on the London Metal Exchange have been as low as £51 and £53 per ton. At these quotations aluminium is cheaper than copper, and electrical companies are contracting for large supplies. The cost of producing aluminium varies with each company, but it is pretty safe to say that at anything under £55 per ton it cannot be sold without actual loss to the manufacturers.

The Brooklands Agreement.—The weakness of the Brooklands Agreement was in its failure to provide for a renewal of negotiations once a strike has begun. Amendments have now been made, with the unanimous consent of the representatives of both employers and workmen, which repair this flaw. It is provided that when a strike has begun the negotiations shall be automatically renewed in the same place in which they were broken off. The first of such meetings is to be held within a fortnight after the strike has begun, and they are to be continued, at intervals of not more than a month, so long as it lasts.

The Agricultural Returns. — The preliminary statement of the Agricultural Returns shows a further reduction by 51,272 acres of the cultivated area of Great Britain, arable land having decreased by 20,986 acres, and permanent pastures by 30,456 acres. The acreage of wheat increased by 97,189 acres, and reached a total of 1,906,043 acres, being a larger area than has been recorded in any year since 1898. The acreage of barley declined 130,734 acres, a smaller total than any previously recorded. There is some indication of a revival in the cultivation of flax, which forty years ago occupied about 20,000 acres, but in recent years has almost disappeared. It is noticeable too, that the acreage of hops, for the second successive year, shows a slight extension, though it is still nearly 12,000 acres less than it was so recently as 1907. The acreage under fruit is stationary.

CORRESPONDENCE.

THE ETYMOLOGY OF NATRON.

With reference to the footnote by Sir Henry Trueman Wood on natron in his most interesting and acceptable paper on "The Royal Society of Arts," Part IV., in our *Journal* of the 29th ult., I should like to add the following remarks to his own on the etymological point raised by him.

"Natron," through Latin "natrum," and Greek *νίτρον*, is ultimately from the Hebrew *nether;* the word used by the Jews to distinguish mineral *alkalis* [Hebrew *Kalah* "to burn," and Arabic *al-Kala*, "the burnt"] in general, from vegetable alkalis, or *borith*. In Proverbs xxv. 20, where the word is translated in the English Authorised Version of the Bible:—"As vinegar upon nitre, so is he that singeth songs to an heavy heart"; and, again, in Jeremiah ii. 22:—"Though thou wash thee with nitre, and take thee much sope, yet thine iniquity is marked before me," obviously "natron," or "neutral carbonate of soda," is meant and not nitre [French form of nitrum]. The *νίτρον* of Herodotus ii. 86, is also undoubtedly our natron. But Pliny, following Theophrastus and others, certainly includes various alkalis under the term. Thus, xix. 26 (5), he tells us that the *Egyts* of Ancient Egypt used "nitrum" to water radishes—"in Ægypto nitro sparguntur"—so famous for the mildness of their flavour. This reads more like nitre, or "nitrate of potash." Then, in xxxi. 46 (10), he writes:—"nitrum closely resembles salt"—"natri natura non multum a sale distans"; which reads more like nitre than soda. Virgil, "Georgics," i. 94, states that the Roman cultivators soaked almonds before sowing them in nitrum and lees of olive oil, that they might bear the larger fruit:—

"Semina vidi equidem multos medicare serentes,
Et nitro prius, et nigrâ perfundere amurca,
Grandior ut fetus siliquis fallacibus esset."

Here "nitrum" might have been "natron." In China to this day, nitre, or saltpetre, and natron are confounded together. Natron is found over all the volcanic areas of India, the "dhobees-earth," used everywhere in that country for washing the clothes of Europeans, being but a crude natural form of nitron, combined with a proportion of muriate of soda. Natron also is largely yielded by "Lake Lunar," the dowsed crater [76° 30′ E. longitude, and 20° N. latitude] whence were poured forth the trappean streams that built up the greater part of the Western and Northern Deccan—the Deccan as distinguished from the Carnatic—when as yet it was still a triangular island, separated from the continent of Asia by the strait now represented by the valleys of the Ganges and the Indus. GEORGE BIRDWOOD.

October 2nd, 1911.

SLAG AND FURNACE REFUSE ORNAMENTS.

Not many years ago a great number of small useful articles were on sale in London, said to be made of slag or furnace refuse, in pretty imitation of onyx and malachite.

Can any member say whether such things can now be bought, and if so, where?

The articles coming under the writer's notice were ash-trays, pin-trays, candlesticks, trinket boxes, inkstands, etc., and were brittle. It would be interesting to learn something of the process of manufacture, and particularly where they were made, and why the general supply in this country ceased. JOHN RYLE.

Brighton.

GENERAL NOTES.

LECTURES ON ILLUMINATING ENGINEERING.—A special course of twelve lectures on Illuminating Engineering, under the direction of Mr. L. Gaster, editor of *The Illuminating Engineer*, will be delivered by Professor J. T. Morris, Mr. J. G. Clark, Mr. E. Scott-Snell, Dr. W. J. Ettles, and Mr. J. S. Dow, at the Polytechnic, Regent Street, on Tuesday evenings, beginning on October 31st, 1911, and on Thursday evenings, beginning on January 11th, 1912. The course will deal with all illuminants,

including electric, gas, oil, and acetylene lighting, the effect of light on the eye, and the hygienic aspects of illumination, the measurement of light and illumination, etc. Practical problems, such as the lighting of schools, streets, factories, etc., will also be treated, and the lectures will be fully illustrated by lantern-slides and demonstrations. A similar course will also be delivered during the coming session at the Battersea Polytechnic.

THE NUMBER OF BICYCLES IN FRANCE.—In 1910 the number of bicycles in France exceeded 2,700,000, and produced a revenue of about 8½ millions of francs (£340,000). The departments having the greatest number were those of the Seine, with 287,422; Nord, 146,449; Seine-et-Oise, 87,539; Pas de Calais, 65,225; Gironde, 64,889; Seine Inférieure, 57,243; Maine-et-Loire, 53,855; Seine-et-Loire, 52,619; Seine-et-Marne, 52,488; Loiret, 50,310. The department with the smallest number was that of Lozère, with only 2,394 cycles.

FOREIGN TRADE OF GERMANY.—The exports and imports of Germany during the first six months of the present year as compared with those of the corresponding six months of 1910 are given in thousand of marks as follows:—

	1910.	1911.	Increase.
Exports . . .	3,646,200	3,847,900	201,700
Imports . . .	4,613,400	4,771,800	158,400
Totals . .	8,259,600	8,619,700	360,100
£ sterling .	£412,980,000	£430,985,000	£18,005,000

The value of the imports in 1911 exceeded that of the exports by 923,900,000 marks (£46,195,000), as compared with 967,200,000 marks (£48,360,000) of the previous year.

IMPORTS OF ARTIFICIAL FLOWERS TO ITALY.—According to the *Bulletin de la Chambre de Commerce française* of Milan, the importation of artificial flowers to Italy is increasing. In 1910 the quantity of these goods imported by that country amounted to 26,259 kilogs. (57,901 lbs.), of which 13,656 kilogs. (30,113 lbs.) were from Germany; 9,805 kilogs. (21,620 lbs.) from France, and the remainder, 2,798 kilogs. (6,168 lbs.) from other countries.

INTERNATIONAL CONGRESS FOR THE OIL INDUSTRY.—An International Congress, under the honorary presidency of the Minister of Agriculture, organised by the Société Nationale d'Oléiculture de France, will be held at Avignon from November 14th to 17th next. The principal subjects to be discussed, on which papers will be read by some of the most eminent French and Italian authorities, will be on the extinction of such pests as the olive fly, the phéothrips, and other parasites which have played such havoc of late years in the olive-growing districts, especially in France and Italy. Interesting papers are also announced on new methods for the extraction and purification of oil from the olive, as well as the results of a new process of extraction of oil in the vacuum (Système Acapuleo), which has been carried out by Professor Mingioli of the Agricultural School of Portici, Naples, for the Italian Government. Excursions will be made to places of interest in the neighbourhood as well as visits to some of the best managed olive estates and oil works, where many of the best known brands of oil are manufactured. Members of the Congress will be entitled to a reduction of 50 per cent. on all railway fares, and to special terms at the principal hotels at Avignon.

THE WINE AND OIL PRODUCTION OF TURKEY.—The production of wine is a growing industry in Turkey, especially in Syria, Palestine, and the Smyrna and Salonica districts. It is estimated that in 1910 the output aggregated some 100,000 tons, most of which was consumed in Turkey and Egypt. Europe (especially Germany and France) and America, however, buy increasing quantities of Turkish wines, both red and white. Wine, next to mother-of-pearl articles, constitutes the principal item of export to the United States from Jerusalem. It is estimated that out of a production of 60,000 tons of olive oil, which is a fair average estimate for Smyrna and the adjoining islands, 15,000 tons are exported, another 15,000 tons absorbed by the Turkish soap industry, and the remainder consumed by the inhabitants, who, in consequence of the increased cost of olive oil, are gradually forced to adopt substitutes (animal fats, etc.) from abroad. Under normal conditions the cost of edible olive oil averages about fivepence per pound, and the total output in the Ottoman Empire amounts to about 75,000 tons. There is a tendency in Turkey now to produce higher grade oil, fit for European and American tables, and this is particularly noticeable in Aivali, Mitylene and Crete.

MEXICAN "COMITECA" LIQUOR.—"Comiteca" is the name given to a spirituous liquor manufactured in Comitan, State of Chiapas, Mexico. It is an exclusively local product, since in no other part of the country is anything similar produced. The species of maguey, or agave, from which it is distilled, thrives only within a radius of ten or twelve miles, outside of which the agave plants have, it is true, certain alcoholic properties, but in comparison are little adapted to the distillation of this class of liquor. Its specific qualities are known only in a few states of the Republic and in Guatemala, as yet the only foreign market in which it has been introduced, owing to the lack of proper means of transport. The liquor is distilled from "pulque," a beverage brewed from the sap of the maguey. To pulque is added a certain proportion of "panacha" (coarse dark sugar), then, for the sake of the tannin, the inner bark of a species of oak, styled in the native Indian dialect "pajulul," and last, distilled water. It is the maguey plant from which the liquor is extracted which gives to the "cometica" the especial flavour and aroma.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

ROCK CRYSTAL: ITS STRUCTURE AND USES.

By ALFRED E. H. TUTTON, M.A., D.Sc., F.R.S.

Lecture II.—Delivered May 8th, 1911.

In order to emphasise the facts referred to in the first lecture concerning the exterior configuration of quartz, we cannot do better than take a characteristic well-formed crystal and measure it on the goniometer, which will bring home the arrangement of the faces in a manner which nothing else could. Such a crystal, actually measured in great detail by the author, is shown in Fig. 8 and its stereographic projection, the plan of its faces, in Fig. 9.

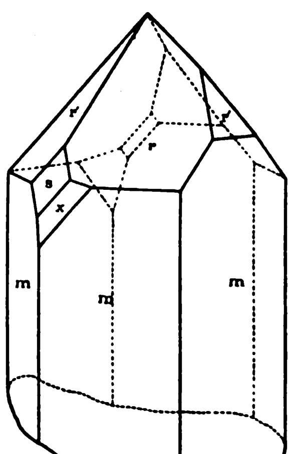

FIG. 8.—MEASURED CRYSTAL OF QUARTZ.

The reflecting goniometer, the principal instrument of the crystallographer's laboratory, consists essentially of an accurately-divided circle, reading with a vernier to single minutes of arc, and which can be made to carry the crystal on its axis of rotation. The crystal is not directly mounted on the central axis, but on a little cone of wax carried at the summit of a series of centring and adjusting movements, the latter consisting of two circular movements at right angles to each other, so that the crystal, which should be very small, the size of small shot or a small pea being suitable, may be brought exactly into the axis of rotation of the circle and adjusted so that the edge between any given pair of faces is parallel to the axis. A collimator, provided with a slit of the kind first recommended by Websky, narrow in its central part for adjustment to the vertical cross-wire of the telescope and broad at the two ends in order to render it more readily visible, is arranged on one side of the circle, and a telescope on the other, both pointing to the axis of rotation and perpendicular thereto, while being parallel to the circle. Reflections of the Websky slit are then arranged by adjustment of the crystal to be afforded in succession from the two faces in question, between which it is

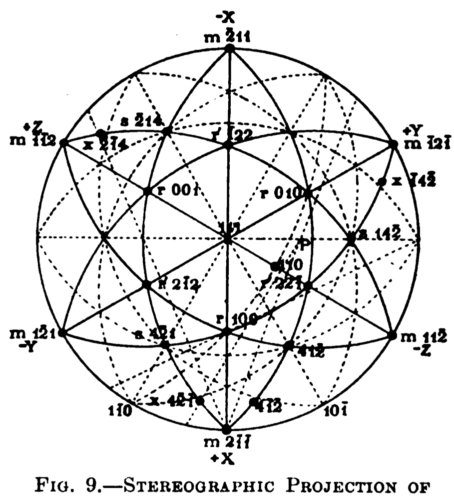

FIG. 9.—STEREOGRAPHIC PROJECTION OF QUARTZ CRYSTAL.

desired to measure the angle, by rotation of the circle with the crystal axis, the telescope and collimator being fixed at some convenient angle, about 120°, for obtaining the reflections. The image of the slit from each of the two faces is then brought in succession to the cross-wires of the telescope, by rotation of the circle (and thereby of the axis and crystal), a reading of the circle being then taken for each position; the angular difference between the two readings is the supplement of the dihedral angle between the two faces, and is the angle between the normals to the two faces, the actual angle marked on the stereographic projection. This will all be clear from Fig. 10, in which *T* is the telescope, *C* the collimator, and *a*, *b*, *c* the crystal, relatively grossly exaggerated in size for the sake of clearness, the face *b* of which is adjusted to give a

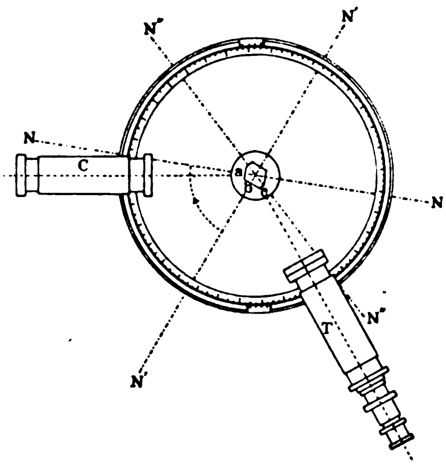

FIG. 10.—DIAGRAM ILLUSTRATING THE PRINCIPLE OF THE GONIOMETER.

reflection of the collimator slit in the telescope. *N′N′* is the normal to the face *b*, while *NN* is the normal to the face *a*, and *N″N″* that to the face *c*. In order to bring the face *a* to give a reflection, for instance, supposing the edge *ab* (the crystal edge between the two faces *a* and *b*) to have been adjusted parallel to the axis of the goniometer, it would be necessary to rotate the crystal through the angle on the left between *NN* and *N′N′*, the angle marked by an arc. The little arrow on the arc indicates the direction of rotation when the angle *ab* is being actually measured, the face *a* being first adjusted as *b* is shown to be in the figure, and the axis rotated until *b* is so adjusted, as shown.

It is much more convenient for the crystallographer to record these angles between the normals to the faces, rather than the dihedral supplements, because he is sure to want to construct a stereographic projection, and it is precisely the positions of these normals with respect to the sphere, the centre of which is supposed also to be that of the crystal as well as the sphere, which are required, the intersections of the normals with the spherical surface being the facial poles, marking the positions of the faces on the projection.

The above facts can now be clearly illustrated by means of our little quartz crystal, Fig. 8, the measurement of the angles of which, and the construction of its stereographic projection, we are going to imagine we are carrying out together.

We will tackle first the obviously hexagonal prismatic zone of faces marked *m* in Fig. 8. The process of adjusting the edge and obtaining reflections of the Websky slit can be grossly demonstrated by a large crystal of quartz, some six inches long, of similar character, the image of a Websky slit placed in front of the electric lantern being reflected from each face in turn on to the screen.

The first thing that strikes us is that not only are these two particular faces adjusted by the adjustment of the edge between them, but that the whole "zone" of six faces of the hexagonal prism are so adjusted, the six faces being all parallel to the vertical axis. The actual angles on our little crystal proved to be 60° within a very few minutes, 8′ being the maximum difference from 60° 0′ in the case of the poorest face, while three of the more perfect faces gave values only differing by a single minute. Hence, there is no doubt whatever that nature intended the zone of faces to be a truly hexagonal one, of exactly 60° 0′ angle. We can, therefore, set out our bounding or "primitive" circle of the stereographic projection, and place dots on it for facial poles at 60° apart.

We may next conveniently measure the angle *mr* between the front *m* and top *r* faces, and on adjusting the edge *mr* parallel to the goniometer axis we find that not only are these two faces *m* and *r* adjusted, but also the parallel face *m* behind the crystal and the smaller pyramidal (rhombohedral) face *r′*. Moreover, the front and back angles *mr* and *mr′* prove to be both 38° 13′, the angle between *r* and *r′* being 103° 34′. We may, therefore, draw a diameter from back to front of the primitive circle in Fig. 9, to represent this zone, and mark on it the two poles *r* and *r′* at their proper positions equidistant from the centre and from the *m* poles. A very simple construction (marking off the angle on the

primitive circle instead of the diameter, and joining the marked-off point to the pole of the other hemisphere, the line of junction cutting the diameter at the facial pole required) enables this to be done on the drawing at once. Similarly, if we measure the angles between other *m* and *r* and *m* and *r′* faces along the two other such zones, represented in Fig. 9 by the two other diameters drawn in strong lines, we find that the angles are always 38° 13′ for *mr* or *mr′* and 103° 34′ for *rr′*, the greatest divergence owing to slight facial distortion never exceeding 6′ in the case of our actual little quartz crystal.

We may now draw circular arcs through the *m* poles on any one diameter and the *r* and *r′* poles on the two other diameters, as shown in Fig. 9, and measure the angles along them, that is, between the actual *m* and *r′* faces belonging to these different cross-zones. When we do so, we discover a further important fact, namely, that the little *s* and *x* faces of the left trigonal pyramid and left trigonal trapezohedron (for our quartz crystal is a left-handed one) are situated in these cross-zones. Thus, to take a single example, when we measure the angle between the front *m* face and the top-front-left *r′* face we come across the images from the faces *x* and *s* which replace this left-hand corner of the crystal, in intermediate positions between the *m* and *r′* images. The actual angles were $mx = 12° 1'$, $xs = 25° 57'$, $sr' = 28° 54'$, altogether making up an angle *mr′* of 66° 52′. These angles are precisely those of the characteristic left trigonal pyramid $s = (4\bar{2}1)$ and trapezohedron $x = (42\bar{1})$ of quartz.

Our little crystal shows a second pair of these *s* and *x* faces on the left-back corner, but the third pair belonging to these two forms were not developed. No such right-handed forms are present at all, however, modifying right-hand top corners of the *m* faces, so that the crystal is clearly a left-handed one.

We have thus actually worked out the symmetry of quartz, and proved it to be trigonal trapezohedral, and that two distinct varieties are possible, a right-handed and a left-handed, our example having been one of the latter variety.

We have thus made perfectly clear to ourselves the external configuration of quartz, and are now attracted by the further problem of the unravelling of the internal structure which is the prime cause of this outward development. There are several very interesting modes of tackling this more difficult problem, the chief of which are the study of the action of solvents on the facial surfaces of the material of the crystal, the nature and shape of the minute internal cavities which the microscope reveals in such abundance, the indications of any cleavage which may be developed, the development of any electrical excitation on heating and cooling again, and, most important of all, the effect of the crystal structure on the passage of light waves through it in different directions.

Considering first the evidence afforded by cleavage, this is very emphatic, in spite of the fact that quartz cleaves with only the greatest difficulty, and then only with the formation of more or less imperfect cleavage surfaces, very different to the perfect ones, as good as the best crystal faces, of calcite. Indeed, this fact of the difficulty of provoking cleavage in quartz, and its rare occurrence naturally, enhances wonderfully the importance and use of the

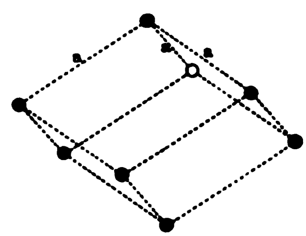

Fig. 11.—Unit Cell of Rhombohedral Space-Lattice.

mineral, both for scientific and industrial purposes; for it enables lenses, prisms, and plates of the mineral to be cut, ground, and polished with the greatest ease, without risk of flaw, and with a most satisfactory result as regards clear transparency and absence of defects. But when a quartz crystal is heated and then suddenly cooled by plunging it into cold water it breaks up into rhombohedra closely resembling cubes, the angle of which is 85° 46′, that of the primary rhombohedron *r* of Figs. 6 and 7. Now it is interesting also that simple apparent cubes, really these rhombohedra, of quartz are occasionally discovered, quite a number having been found in the neighbourhood of Bristol.

These facts afford not only most valuable confirmation of the trigonal as distinguished from possible hexagonal symmetry of quartz, but also indicate that the space-lattice structure present is that of the rhombohedron, the elementary cell of which is represented in Fig. 11.

Thus we conclude that if each molecule SiO_2 were represented by a point, the points would be arranged in the form of a rhombohedral

space-lattice having the angle of the rhombohedron of quartz, 85° 46′.

If we take the hexagonal section of a prism of quartz, and heat it gently and evenly over a small Bunsen flame or other source of heat, and then allow it to cool, electrical excitation is developed, positive and negative electricity being produced respectively at alternate corners of the hexagon. Now the three digonal axes of symmetry emerge at the six corners, and the little trigonal pyramid and trapezohedron faces *s* and *x* are present at alternate corners corresponding to one end only of each axis, and it is interesting that these corners where the little distinctive faces are present are those which become negatively electrified, while those corners where no *s* and *x* faces are developed become positively electrified. This disposition of the pyroelectric poles is precisely in accordance with the symmetry of the trapezohedral class of trigonal symmetry, and of no other, thus confirming our conclusions based on other considerations. These facts can be readily

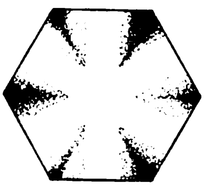

FIG. 12.—DISTRIBUTION OF SULPHUR AND RED-LEAD ON ELECTRIFIED HEXAGONAL PLATE OF QUARTZ.

verified by scattering a little of Kundt's powder, the well-known mixture of red-lead and sulphur, from a muslin bag over the hexagonal plate of quartz cut perpendicularly to the axis during cooling after the heating. On tapping the plate, the sulphur, which has become negatively electrified by friction with the muslin, will be attracted to the positively-electrified corners, while the red-lead, which becomes positively electrified, goes to the negatively-electrified corners. Fig. 12 will render this quite clear.

If we treat a pair of quartz crystals, right and left-handed respectively, with a small quantity of aqueous hydrofluoric acid, which is a chemical solvent for silica, characteristic little markings or "etch-figures," are produced on the faces. Fig. 13 shows the effect on a right-handed crystal, and Fig. 14 that with a left-handed one. The markings are little depressions, of the shape of a candle flame blown to one side by a draught of air, and are pointing upwards and downwards respectively on alternate faces. The etch-pits on the front *m*-face are turned somewhat to the right on a right-handed crystal and to the left on a left-handed crystal. Thus we have trigonal rather than hexagonal symmetry again demon-

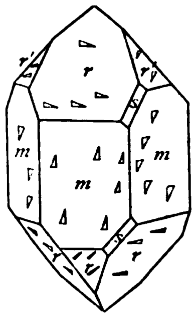

FIG. 13.—ETCH-FIGURES ON RIGHT-HANDED QUARTZ.

strated, and a screw structure, which may be either clockwise or anti-clockwise, such as corresponds to the trapezohedral class of the trigonal system, also most clearly indicated.

An interesting subject intimately connected with etch-figures is that of the shape of internal cavities in quartz. A remarkable example is shown reproduced in Fig. 15, which takes the form of a hexagonal prism capped by a pyramid, a kind of negative crystal of quartz. This cavity is filled, except for a bubble of water vapour, by a saturated solution of common salt, sodium chloride, from which a perfect little cube of salt has crystallised out. Such cavities are not at all uncommon in quartz, and are clear indications of the arrangement of the structural units, and a definite proof that the structure

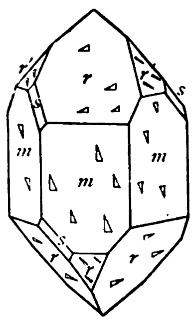

FIG. 14.—ETCH-FIGURES ON LEFT-HANDED QUARTZ.

developed at the exterior is the same throughout —that is, that the crystal is a homogeneous structure. The fluid contents are not always solutions of ordinary common salt, but of other well-known salts such as potassium chloride

and occasionally the liquid is compressed carbon dioxide, a fact which is proved by the disappearance of the bubble when the crystal is warmed to 32° C., the critical temperature of carbon dioxide, above which it is no longer capable of remaining liquid but becomes gaseous. Myriads of such small cavities occur in many quartz crystals, often in strings, and are clearly visible in the quartz crystals present in rock-sections, when examined under the microscope, and with a quarter-inch objective their shape may be readily studied. Those which take the form of negative crystals remind one of the hexagonal stars, or "water-flowers," produced in a slab of lake ice by the passage of the heat rays accompanying the beam of light from an electric lantern, and which make such pretty and instructive objects on the screen. Their explanation is probably

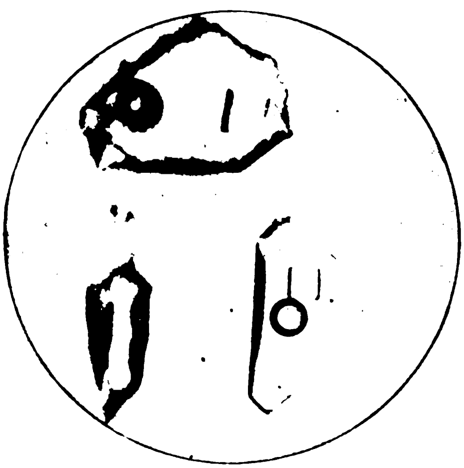

FIG. 15.—NEGATIVE-CRYSTAL CAVITY IN QUARTZ.

similar, namely, that the molecules of the substance, SiO_2 in the case of quartz, and H_2O in the case of ice, are taken down from their homogeneous structure in regular order, revealing the plan of construction of the crystal edifice.

It has thus been shown that the whole of the morphological characters of quartz, both those concerning the disposition of the exterior crystal faces and those directly concerning the internal structure such as cleavage, etch-figures, and the shape of internal cavities, all agree in pointing to a helical arrangement of the ultimate structural units, the chemical atoms of which the molecules of silica are composed.

We may now inquire, therefore, what evidence there exists as to the precise structure of quartz, beyond the fact already elucidated that the molecular structure, that is, the arrangement of the molecules considered as points, is that of the rhombohedral space-lattice. There is considerable evidence now accumulated, but in order to appreciate it reference must be made to two important advances which have been made in our knowledge of crystal structure in general, namely, the completion of definition of the possible types of homogeneous structures, of which there prove to be no less than 230, and the proof of the fixity of the positions of the atoms in the structure, and the allocation to them of definite portions of space, their spheres of influence.

It has already been indicated that the point or node of the space-lattice representing the molecule is, unless the substance be that of a chemical element, in reality the representative point (say centre of gravity) of a cluster of atoms, that which composes the chemical molecule. Now each atom of the cluster may be represented by a point, or it may be represented by its sphere of influence in such a manner that all the spheres of influence are in contact. Considering its representation by a point, Sohncke showed that there are sixty-five homogeneous arrangements of points conforming to the symmetry of the known classes of crystal symmetry. It was subsequently shown, however, by three other independent investigators, Schönflies in Germany, von Fedorow in Russia, and Barlow in England, that these sixty-five cases do not by any means exhaust the possibilities, and that, in fact, they do not account for all the thirty-two crystal classes. They pointed out that an important principle, that of mirror-image symmetry, had been left out of consideration, and that when this is introduced into the case 165 more types of homogeneous structures are possible, making 230 types in all, and that the whole of the thirty-two classes of symmetry are then accounted for, and no more than thirty-two are possible.

Speaking generally, therefore, it is the arrangement of the chemical molecules in a specific space-lattice which determines the crystal system, while the arrangement of the atoms in the molecule determines the details of the systematic symmetry, that is, the particular class. It is thus the stereometric arrangement of the atoms which gives rise to the ultimate symmetry, and the fact that the molecular clusters of atoms form a space-lattice has been liable to be overlooked. Indeed, the fact that the identification of the molecule in the crystal structure is geometrically unnecessary for a time so obscured the influence of the chemical molecule that the very existence of a molecular

directive force of crystallisation, that which brings the molecules together to form the crystal, was actually denied. But the researches of Lord Kelvin, Miers, Wulff, the lecturer, and particularly of Lehmann, who has introduced us to the marvellous phenomena of "liquid crystals"—substances more correctly described as mobile crystals, which may be as mobile as water and yet exhibit an outward form resembling that of a true crystal and the property of double refraction, and the molecules of which arrange themselves in space-lattices—have corrected this misconception. We now realise that although the atomic arrangement determines the detailed crystal structure, and many of the obvious optical properties such as rotation of the plane of polarisation, yet the underlying molecular space-lattice is none the less there.

Sommerfeldt has recently suggested that a model of the space-lattice is really alone necessary to portray the crystal structure, provided that at each of the nodes some device such as a little rod or bar be placed to indicate the kind of atomic arrangement, whether parallel, alternate, or otherwise orientated, as the mere space-lattice alone supposes that the node-points represent parallel-wise orientated units. That the space-lattice is fundamentally important is certain, and that the molecule is a distinct individuality, although in the solid crystal it loses its mobility, is equally now incontrovertible.

Reverting now to the second advance, it has been definitely proved by the lecturer that specific atoms of the molecule are definitely orientated in the crystal, and that if such atoms,

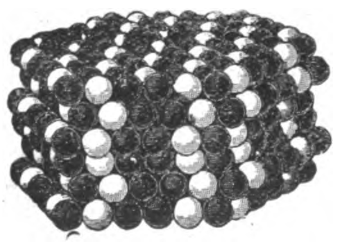

FIG. 16.—BARLOW'S CONCEPTION FOR RIGHT-HANDED QUARTZ.

say those of potassium or of sulphur in potassium sulphate, be replaced by others of the same family group of chemical elements, for instance, the potassium by rubidium or cæsium and the sulphur by selenium, specific directional changes in the crystal angles are observed to occur. In the cases just referred to, the replacement of the metal brings about an alteration in the length of the vertical axis of the rhombic crystal of the sulphate or selenate, while replacement of the sulphur by selenium causes an equatorial change. If, therefore, we accept the view of Barlow, and represent the atoms by their spheres of influence, we are only logically following up this important experimental fact.

Now, recently Barlow has propounded the view, in collaboration with Pope, that the relative size of the sphere of influence of the atom

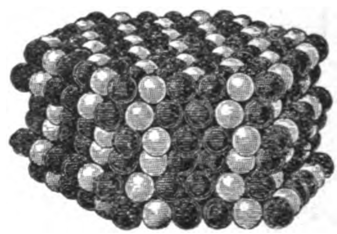

FIG. 17.—BARLOW'S CONCEPTION FOR LEFT-HANDED QUARTZ.

in any one compound, compared with that of any other atom in the same compound, is intimately connected with the chemical valency of the element, and that the dimensions of the sphere of influence are proportional to the fundamental valency. This "fudamental valency" is rarely the maximum valency, although in the case of carbon it would appear to be the latter, atomic spheres of influence of carbon having apparently four times the volume of those of hydrogen or chlorine present in the same compound. To us the cases of oxygen and silicon will at once appeal, and the relative size of the atomic sphere of influence of oxygen appears to conform to its usual dyad character. Silicon might, perhaps, from its occurrence in the same family group of elements as carbon, be expected to behave also as a tetrad, but there is much more evidence that its fundamental valency is only dyadic. Now Barlow has shown that if we accept the view that the fundamental valencies of both silicon and oxygen are dyadic, and therefore that the spheres of influence of the two elements in quartz are of the same size, the whole of the properties of quartz can be explained on the assumption that the two structures, right-handed and left-handed, are composed of such assemblages as are shown in Figs. 16 and 17, in which the white spheres represent silicon and the black ones oxygen atoms, there being two of the latter to every one of the former, corresponding to the formula SiO_2.

The helical character is clearly shown by these assemblages of silicon and oxygen atoms, the white spheres of the former being obviously

arranged in a right-handed screw in Fig. 16, and in a left-handed helix in Fig. 17, the two arrangements being the mirror-images of each other, as a right-hand glove is to a left-hand one. That some such structural arrangements of the chemical atoms as these are really present in the two varieties of quartz is, indeed, highly probable, and the optical properties of rock crystal, to be discussed and demonstrated in the next lecture, will be shown to lend strong confirmation to this view.

Before leaving this fascinating subject of the actual internal structure of a quartz crystal, it is interesting to recall that Lord Kelvin, in his Boyle lecture to the Oxford Junior Scientific Club in the year 1893, gave a remarkable geometrical conception of that structure. He said: "Make an equilateral equiangular hexagonal prism, with its diagonal from edge to edge ninety-five-hundredths of its length. Place a number of these close together, so as to make up a hexagonal plane layer with its sides perpendicular to the sides of the constituent hexagonal prisms. You see in each side of the hexagonal assemblage edges of the constituent prisms, and you see at each corner of the assemblage a face, not an edge, of one of the constituent prisms." (See Fig. 20 and imagine the little projecting or recessive semicircles absent and replaced by their diameters in continuation of the hexagons.) "Build up a hexagonal prismatic assemblage by placing layer after layer over it with the constituent prisms of each layer vertically over those in the layer below; and finish the assemblage with a six-sided pyramid by building, upon the upper end of the prism, layer after layer of diminishing hexagonal groups, each less by one circumferential row than the layer below it. You thus have a crystal of precisely the shape of a symmetrical specimen of rock crystal, with the faces of its terminal pyramid inclined at 38° 13′ to the faces of the prism from which they spring. But the assemblage thus constituted has senary (hexagonal) symmetry. To reduce this to ternary (trigonal) symmetry, cut a groove through the middle of each alternate face of the prismatic molecule, making this groove in the first place parallel to the edges; and add a corresponding projection, or fillet, to the middles of the other three faces, so that two of the cylinders similarly oriented would fit together, with the projecting fillet on one side of one of them entering the groove in the anti-corresponding side of the other. . . . We have then the three-pair anti-symmetry required for the piezo-electricity of quartz investigated so admirably by the brothers Curie, who found that a thin plate of quartz crystal, cut from any position perpendicular to a pair of faces of a symmetrical crystal, becomes positively electrified on one side and negatively on the other when pulled in a direction perpendicular to those faces. But this assemblage has not the chiral piezo-electric quality discovered theoretically by Voigt, and experimentally by himself and Riecke, nor the well-known optic chirality of quartz.

"Change now the directions of the grooves and fillets to either of the oblique configurations shown in Fig. 18, which may be termed right-handed because the directions of the projections are tangential to the threads of a three-thread right-handed screw, and Fig. 19, which may be called left-handed. The prisms with their grooves and fillets will still all fit together if they are all right-handed, or all left-handed. Fig. 20 shows the upper side of a hexagonal layer of an assemblage thus composed of the right-handed molecule of Fig. 18. A prism built up of

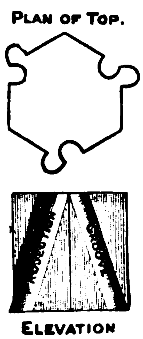

FIG. 18.—LORD KELVIN'S CONCEPTION FOR RIGHT-HANDED QUARTZ.

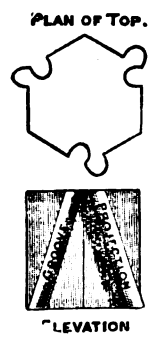

FIG. 19.—LORD KELVIN'S CONCEPTION FOR LEFT-HANDED QUARTZ.

such layers, and finished at each end with a pyramid according to the rules already referred to, has all the qualities of ternary (trigonal) chiral symmetry required for the piezo-electricity of quartz; for the orientational differences of the alternate pairs of prismatic faces; for the absolute difference between the alternate pairs of faces of each pyramid which are shown in the etching by hydrofluoric acid; for the merely orientational difference between the parallel faces of the two pyramids; and for the well-known chiro-optic property of quartz."

Lord Kelvin on the occasion of this lecture showed two beautiful models, one of a right-handed quartz crystal, built up of the right-handed constituent grooved and filleted hexagonal prisms of the character and

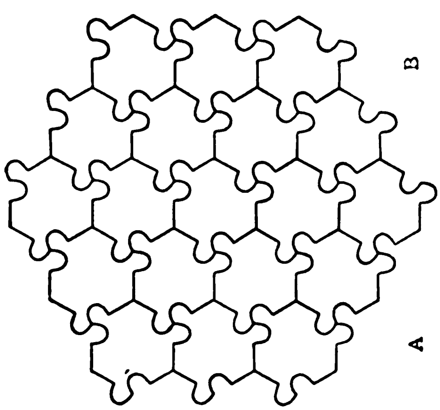

FIG. 20.—A RIGHT-HANDED LAYER OF LORD KELVIN'S ARRANGEMENT.

dimensions just stated, in accordance with Figs. 18 and 20, and another of the complementary left-handed character. The projecting fillets and retrogressive grooves may be taken as a gross geometrical device to indicate the helical arrangement of the elementary atoms, clusters of which corresponding to the chemical formula SiO_2 are built up on the plan of a trigonal space-lattice. Such helical arrangement of the atoms themselves is beautifully indicated in Barlow's conception of the arrangement of the spheres of atomic influence as shown in Figs. 16 and 17, and the author understands, from recent conference with Mr. Barlow, that further work on the subject has only more fully convinced him of the probability that these two arrangements of Figs. 16 and 17 do really represent the character of the internal structure of the two varieties of quartz.

NICE AS PORT OF CALL FOR OCEAN LINERS.

Although Nice can have no pretension to rival either Marseilles or Genoa as a commercial port, it is quite possible in the near future she may become a port of call for ocean liners.

Unlike Marseilles, with the valley of the Rhône and the centre of France at her back, or Genoa in direct communication by rail with Milan and Lombardy, as well as with Switzerland and Germany *via* the St. Gothard tunnel, Nice has no *hinterland* to support a large export or import trade. On the other hand, from her unrivalled position as Queen of the Riviera, she will always command a large and increasing passenger traffic.

Nice now numbers 168,000 inhabitants, and is 140 miles by rail from Marseilles and 115 miles from Genoa.

The actual port of Nice, or *Port Lympia*, is situated to the east of the "Chateau," in the old town. It consists of an outer and an inner harbour, covering an area of about fifteen acres of water. The length of the existing quays is about 650 metres (2,150 ft.). The entrance is protected from the south-west winds by a breakwater, and is well sheltered on other sides by hills and mountains. This port is only frequented by coasters and vessels drawing not more than 5·80 metres (19 ft.), and is of only local importance, and quite unsuitable as a port of call for liners.

This being the case, Nice may be considered as particularly fortunate in possessing, almost at her door—in Villefranche—a port suitable for vessels of large tonnage. Scarcely three miles from the railway station of Nice, the gulf of Villefranche, with deep water extending close in shore, is one of the finest natural harbours on the Mediterranean coast. It is much frequented by war vessels of all nationalities, the roadstead being well protected on three sides by hills and mountains, and affording excellent anchorage.

The growing importance of Villefranche as a port of call, may be gathered from the fact that, during last season, December 1st to March 31st, no fewer than twenty-four calls were made by ocean liners of 168,400 aggregate net tonnage, landing 1,051 and embarking 802 passengers and their luggage.

The landing was effected by means of a steam tender from the ship to a pontoon moored at the outer end of the mole or breakwater of the existing little port, which is situated at the north-west corner of the gulf.

Amongst the largest of these liners may be mentioned the "Cedric" and "Celtic" of 13,500 net tons each, and the "Arabic" of 10,000 net tons, belonging to the White Star line. The Cunard line was represented by the "Franconia" of 11,200 net tons (which called twice); the "Caronia," 9,000 tons (called once); the "Carmania," 10,000 tons (three times); and the "Saxonia," 9,800 tons (once). Of the other companies which used this port for landing and embarking passengers and a

small quantity of freight, may be mentioned the Peninsular and Oriental, the Hamburg-American line, the Fabre line of Marseilles, and the "Thelia," a steamer belonging to an Austrian line.

It is anticipated that no fewer than thirty liners belonging to various steamship companies will touch at this port during the coming season. Of these, 146,900 net tons will belong to ships of the White Star and the Hamburg American lines; while the tonnage of the vessels of the Cunard, Fabre, Peninsular and Oriental, and the Oriental Austrian Lloyds, will probably bring up the total to upwards of 250,000 net tons.

In order to provide further facilities for landing and embarking passengers, it will be necessary to extend the present mole or breakwater into deeper water, and so obviate the necessity of transhipment into a steam tender; to provide more ample accommodation for the examination of luggage by the Customs authorities than has existed hitherto, and to convey the passengers after landing rapidly to their destinations in Nice.

The local authorities are fully aware of this fact; and, thanks to the energy of the Mayor of Villefranche, M. Binon, the enlargement of the Quai de la Santé, close to the landing-place, is already well in hand. The new Custom House building, with commodious waiting and examination room, to be erected on the quay, has now been commenced. Ample space will be provided in front of the Custom House for fifty or sixty autobuses from the various hotels, to await the arrival of the passengers and to convey them to Nice in about half an hour.

Various projects for the construction of a deep-water harbour at Villefranche have been proposed. These schemes consist mainly in the construction of a breakwater 700 to 800 metres (about 2,300 to 2,600 ft.) in length, in a south-east direction, from the western shore, extending into a depth of water of about 25 metres (13½ fathoms) at its outer end. The entrance to the harbour would be about 200 metres (about 650 ft.) in width, with a depth of 20 metres (10¾ fathoms).

The extent of water thus enclosed would be well sheltered from the *Libeccio* (south-west) winds, whilst Monts Boron, Ferrat, and the Maritime Alps would afford complete shelter on the other sides.

The harbour thus formed would cover an area of 35 hectares (86½ acres) of water, with a depth, for the greater part, of more than 15 metres (about 8 fathoms). The quays would have an extension of 2,500 metres (about 8,200 feet run), with a depth alongside of 5½ fathoms.

One scheme includes a tunnel of about a mile in length under the Col de Villefranche, running parallel to the existing railway tunnel between Villefranche station and Nice, with branch lines and sidings to connect the port with a new goods station to be established in the suburb of St. Roch, on the left bank of the torrent Paillon. This part of the scheme would certainly not be required for many years to come, and not until the export and import trade of the port rendered the expenditure advisable.

The cost of such a work, of which more than half would be spent on providing railway accommodation, and not on harbour works proper, has been estimated at 17 millions of francs (£680,000).

THE FIVE HUNDREDTH ANNIVERSARY OF THE FOUNDATION OF THE UNIVERSITY OF ST. ANDREWS.

Sir John Cameron Lamb, C.B., C.M.G., Vice-President, and late Chairman of the Council, represented the Society at the celebration of the Five Hundredth Anniversary of the Foundation of the University of St. Andrews. The celebrations continued from September 12th to 16th, and were attended by between three and four thousand guests, including delegates from over a hundred universities and the leading learned societies of the world. The proceedings opened on the evening of the 12th with a reception by the Chancellor of the University, Lord Balfour of Burleigh. On the following morning the staff of the university and the delegates assembled in the quadrangle of the United College of St. Salvator and St. Leonard, and marched in procession to the town church, where a solemn service of thanksgiving was held. The scene was very impressive, owing to the distinguished character of many of those present, and the extraordinary brilliance of the academic and civic costumes. Some of the robes of the German professors were over two hundred years old, and one, at least, had been insured for the sum of £1,200.

In the afternoon the Chancellor, after reading a letter from King George V., in which his Majesty expressed his regret at being unable to be present at the celebration, and his deep sense of the national significance of the event, delivered an address of welcome to the guests—"the members of more than one hundred universities, and upwards of forty other societies, who have responded to our call from British dominions all over the world, from the United States, from Austria, Belgium, Denmark, France, Germany, Greece, Holland, Hungary, Italy, Norway, Russia, Sweden, Switzerland, and Turkey." The Chancellor's speech was followed by the presentation of addresses to the university by the delegates. In the evening the students gave, before a vast audience, a series of tableaux, depicting scenes from the history of St. Andrews.

The first ceremony on the 14th was the installation of the Lord Rector. Lord Rosebery, who had arrived at the harbour in his private yacht, and had been drawn by the students in an open carriage to the Principal's residence, delivered a brilliant oration on the state of Scotland in the fifteenth century, and the part played by St. Andrews in its subsequent history. After this, honorary degrees were conferred on a number of the delegates (including Mr. Asquith), and in the evening a banquet

was held, attended by some five hundred guests, at which the principal speakers were Mr. Balfour and Lord Rosebery.

On the 15th the guests proceeded to Dundee, whose University College forms part of the University of St. Andrews. After listening to further speeches from the Chancellor and the Lord Rector, the visitors were entertained at luncheon. A large ball given in the evening at St. Andrews brought the brilliant and memorable celebrations to an end.

HOME INDUSTRIES.

The Coal Mining Industry.—The Miners' Federation Conference has unanimously decided to support the demand of the Northumberland miners for a new wage agreement with a fixed wage minimum of 30 per cent. above the 1879 basis, and the abolition of the three-shift system. The principle of a fixed minimum wage for coal-hewers has been in operation in the English federated districts since 1894, and is now conceded in the wage agreements made in Scotland and south Wales. The 1879 basis for Northumberland meant 5*s.* 2*d.* a day, with a percentage based on the selling price of coal for the moment. That percentage is now 27½, and added to the 5*s.* 2*d.* makes the total roughly 6*s.* 6*d.* a day. What the miners now seek is an advance to 6*s.* 8*d.* a day, and a guarantee that the 6*s.* 8*d.* be a minimum for the future. As to the abolition of the three-shift system, the Northumberland miners say it imposes intolerable conditions on the home life of the miners. In some quarters a national stoppage of work is thought probable, and much will depend upon whether the Coal Owners' Association consents to a joint meeting to discuss the proposals. The conference of the Miners' Federation has shown that there is a cleavage between the moderate men and those who would precipitate a national strike as the best means of obtaining the changes demanded by the miners.

Pit-Brow Women.—There is sharp division of opinion between the labour leaders and women workers as to the clause in the Coal Mines Bill abolishing female labour at the pit-banks. On behalf of the Government, Mr. Masterman has promised that it shall be deleted, but at the Miners' Federation Conference held last week the following resolution was carried unanimously: "That this Federation make a special effort to preserve the Mines Bill as it passed through Committee on the abolition of female labour on pit-banks in future, and also the weekly payment of wages to workmen." The clause as it stands does not throw out of employment those now engaged at the pits, but requires that no other women be so employed. Notwithstanding this limitation, strong efforts will be made by the representatives of women workers to prevent Parliamentary interference with pit-brow workers, and it is proposed to hold a meeting in London on October 31st, at which twenty or thirty of the workers will be present to remove false ideas about their dress and appearance. Whatever else may be said against the work it cannot be said to be unhealthy, and its prohibition would be a serious loss to many households in certain districts. Opinion is much divided on the subject, but the great majority of the miners' representatives in the House of Commons will probably go into the lobby against the employment of women at the pits. That, however, is not conclusive as against their employment, and probably the dispute will end in a compromise which will impose some restriction in substitution for the abolition clause. The case for the women could not be more effectively put than it was by Mrs. Alfred Haworth, who spoke at a meeting held last week at Manchester to protest against the abolition of the work of women at the pit-brow. Referring to the deputation that recently waited on Mr. Masterman, to which reference has been made in these Notes, Mrs. Haworth said: "The deputation consisted of forty or fifty of the pit-brow women themselves. They had with them a doctor to testify to the healthiness of the work, and a clergyman to testify to the good morals of the workers, and they had also the manager of one of the pits. When they got to the House of Commons they were joined by a number of friendly members, including Mr. Stephen Walsh, an ex-miner himself and the member for Ince. It was an extraordinarily effective deputation. It proved a number of things; and, first of all, that work at the pit-brow was healthy work. No doctor in the neighbouring towns could be found who knew of any special illness among the women, and no lawyer could be found who knew of any case of injury having been taken into court under the Workmen's Compensation Act. It was proved, indeed, that the doctors of the neighbourhood were in the habit of recommending this work as healthy work for people who were inclined to consumption or anæmic, and it was said that of ninety workers at one pit thirty were actually there under doctors' orders. As regarded the conditions of work, the hours were short for a woman worker, eight hours a day for five days in the week, and the pay was comparatively good, the average wage being about 12*s.* a week. As to morals, Mr. Masterman said at once that there was no necessity whatever to go into that subject. Mr. Masterman promised the support of the Government in trying to delete this amendment when the Bill got back to the House of Commons, but he spoke of the possibility of certain regulations being made affecting the work of the women." Mrs. Haworth understood that the women did not want any regulations at all.

Cotton Statistics.—The statistics just published by the International Federation of Master Cotton Spinners' and Manufacturers' Associations give the total number of spindles throughout the world as 137,278,752. The estimated number of spinning spindles in Great Britain is given as 54,522,554. Of this number, 39,977,255 are mule spindles, and 8,050,925 ring spindles. Egyptian cotton is used

by 13,169,923 spindles, and 34,858,237 spindles are engaged on American, East Indian, and sundry cottons. At the present time there are in course of erection in Great Britain 896,934 spindles. The curtailment of production during the past season amounted to 113 hours in Great Britain, 140 hours in Germany, 105 hours in France, 419 hours in Austria, 339 hours in Italy, and 180 hours in Switzerland. The consumption of cotton per 1,000 spindles is 70·47 bales in Great Britain, 105·23 bales in Germany, 132·99 bales in France, 352·15 bales in India, and 162·65 bales in the United States. The stocks on August 31st of all kinds of cotton throughout the world are given as 2,619,052 bales, against 2,523,782 bales at the same time last year. The stock of American cotton is stated to be 1,135,166 bales, as compared with 1,123,526 bales twelve months ago. The consumption during the season ended August 31st last of all spinners throughout the world amounted to 17,819,070 bales, as against 17,030,511 bales during the previous year. The figures for American cotton are 11,559,401 bales, as compared with 11,145,678 bales during the previous year.

Shipbuilding.—In September the Scottish shipbuilders put into the water 54,427 tons, an amount that has only once been exceeded in a corresponding month. The total output for the Clyde yards in the nine months ended September was 195 vessels, representing 432,218 tons. These figures have only twice been exceeded, namely in 1906 by 30,000 tons, and in 1907 by 25,000 tons, and the work remaining on hand is said to be greater than the work which has been turned out during the year so far. Moreover, there are a number of contracts in negotiation. All the new ships are said to have found immediate employment, and there is still a demand for tonnage, but it remains to be seen what effect the war will have on freights. If it continues it can hardly fail to check over-sea contracts, but, meantime, shipbuilders are busy and shipowners doing fairly well.

Railway Rates.—The Manchester Chamber of Commerce has succeeded in bringing about an important concession in the railway rates for cheese and other dairy produce from the south of Scotland. The rate on cheese from Montreal to Manchester is 20*s.* a ton, but until last month the rate on cheese from the south of Scotland to Manchester was 35*s.* per ton, no matter how large a quantity was sent, whilst for margarine and "half-meat" cheese from the same district a special rate of 26*s.* 3*d.* per ton was granted, subject to the proviso that they must be in two-ton lots. It will be seen from these figures how greatly the Scottish farmers have been handicapped in competing with Canada for the cheese market. The two railway companies concerned have now granted a rate of 26*s.* 8*d.* all round, a rate now in force, and the restriction as to consignments of butter being necessarily in two-ton lots has been removed.

Jute.—A chart issued by Messrs. Joseph J. Barrie & Co., of Dundee, gives some suggestive figures bearing upon the present position of jute. Last year the crop was just under 8,000,000 bales, the consumption 8,497,774 bales. For the current season the estimate is of a crop of 8,319,700 bales, and the world's requirements are put at 9,240,703 bales. It would seem, therefore, that the supply of jute will not be equal to the demand, and a rise in price may be expected, and maintained until better crops replenish the supplies.

The National Insurance Bill.—If the statements of Ministers who have recently referred to the subject are to be taken as representing the final intentions of the Government, the Insurance Bill is to be passed through the House of Commons before the session closes, but the opposition to it continues to expand and deepen. Whilst influential sections of the labouring classes are actively opposing it, there does not appear to be enthusiasm for it anywhere. Take, for example, the numerous class which include warehousemen, salesmen, buyers, travellers, clerks, book-keepers, cashiers and others in receipt of a salary of not more than £160 per annum. They will come under the provisions of the Insurance Bill whether already voluntarily insured for sickness or not. They will have to pay 4*d.* per week, and their employers will have to pay 3*d.*, whilst the State adds 2*d.* per head, but the benefits do not appear to be commensurate, or anything like equal to those now given by the various provident associations of the country for a contribution of 6*d.* per week. But poor as are the benefits for friendly society members, they are considerably worse for those who are not members of such societies, for the thirteen weeks' benefit of 10*s.* per week and the thirteen weeks' benefit at 5*s.* per week during sickness only refer to those who are assured through "approved" societies. Others than these can only draw sickness benefit to the amount of their contributions less expenses of management, medical, and sanatorium fees, which means that such persons can only accumulate to their credit each year about £2 6*s.* to be drawn upon in sickness.

OBITUARY.

Frederick Braby, F.C.S., F.G.S.—By the death of Mr. Frederick Braby, which took place at his residence in Teddington on the 9th inst., the Society has lost a member of over fifty years' standing, he having been elected in 1859. He was the head of the firm of Messrs. Braby & Son, manufacturers of corrugated iron, whose large works at Deptford and elsewhere are well known; and he was conspicuous for his generous treatment of his employees and for his local benefactions. He published several works, amongst them being "A Wonderful House and its Tenant."

Sir Charles Bennet Lawes-Wittewronge, Bart.—Sir Charles Lawes-Wittewronge died on the 6th inst. at Rothamsted, Hertfordshire, after an operation for appendicitis. He was the son of Sir John Bennet Lawes, Bart., F.R.S., the famous agriculturist, who, with Sir Henry Gilbert, in 1893 received the Albert Medal of the Society "for their joint services to scientific agriculture, and notably for their researches, which, throughout a period of fifty years, have been carried on by them at the Experimental Farm, Rothamsted."

Born in 1843, young Lawes—he only assumed the additional name of Wittewronge in 1902—was educated at Eton and Trinity College, Cambridge. Here he distinguished himself greatly as an athlete, winning the first inter-University mile race in 1864, and becoming amateur champion for one mile in the following year. He also stroked the Cambridge eight in 1862, and won the Diamond Sculls at Henley in 1863, and the Wingfield Sculls in 1865. In later years he took up cycling with great enthusiasm, and held the amateur records for various distances up to twenty-five miles.

On leaving Cambridge, he devoted himself to sculpture, and exhibited numerous figures and busts. Perhaps his best-known work is the colossal group, "Dirce and the Bull," which is at present the central object in the Gallery of British Sculpture in the Rome Exhibition. He worked unremittingly at his art, and his interest in his profession was further shown by the help he gave towards founding the Society of Sculptors, of which he was the first president. Outside his studio his chief interest was the Lawes Agricultural Trust, of which he was chairman at the time of his death. He became a member of the Society in 1901.

GENERAL NOTES.

Production of Feathers in France.—Feathers form an important item of profit, judging from the following annual returns made by the wholesale dealers (" marchands de volailler en gros ") of sixty-eight out of the eighty-six Departments of France. No statistics are available for the remaining eighteen, which includes Paris and the Department of the Seine. No estimate can be given of the value of the feathers of poultry sold direct by producer to consumer.

	No. head.	Metric tons Weight.	Value. Francs.	£ sterling.
Geese	1,815,000	470	4,700,000	188,000
Turkeys	980,000	344	860,000	34,400
Ducks	1,680,000	140	560,000	22,400
Pigeons	1,210,000	70	280,000	11,200
Domestic Fowls (cocks and hens)	36,680,000	3,060	2,870,000	114,800

22,500 persons are engaged in the sixty-eight Departments in the purchase and plucking of the fowls, and 2,800 in sorting and preparing the fowls for sale.

State Insurance in England and Abroad.—A course of twelve lectures on this subject will be given at the London School of Economics, Clare Market, W.C., by Sir Edward Brabrook, C.B., Mr. H. B. Lees Smith, M.P., Mr. A. W. Watson, Mr. C. S. Loch, B.A., D.C.L., LL.D., Miss Marion Phillips, D.Sc. (Econ.), and the Hon. W. P. Reeves, Director of the School, on Mondays at 5 p.m., beginning on October 16th. The first lecture will be open to the public without fee.

MEETINGS FOR THE ENSUING WEEK.

Monday, October 16...Architectural Association, 18, Tufton-street, S.W., 7.30 p.m. Mr. R. Unwin, "Town Planning, Formal or Irregular."

Tuesday, October 17...Faraday Society, at the Institution of Electrical Engineers, Victoria-embankment, W.C., 8 p.m. Discussion on following papers:— 1. Mr. J. Harden, "The 'Paragon' Electric Furnace and Recent Developments in Metallurgy." 2. Mr. Donald F. Campbell, "Progress in the Electrometallurgy of Iron and Steel." 3. Mr. E. Kilburn Scott, C.E., "The Hering 'Pinch Effect' Furnace."

Sociological, at the Royal Society of Arts, 18, John-street, Adelphi, W.C., 8.15 p.m. Mr. G. S. Lee, "The Bearing of Social Imagination upon Wealth."

Wednesday, October 18... Microscopical, 20, Hanover-square, W., 8 p.m. 1. Mr. T. W. Butcher, "Structural Details of Coscinodiscus asteromphalus." 2. Mr. A. Flatters, "Abstract of Paper on the Wheat Plant." 3. Rev. Hilderic Friend, "New British Enchytraeids." 4. Mr. Walter Bagshaw, "Instantaneous Exposure in Photo-micrography."

United Service Institution, Whitehall, S.W., 3 p.m. Mr. C. E. D. Black, "A Proposed Railway from Egypt to India."

Thursday, October 19...Child Study, 90, Buckingham Palace-road, S.W., 8 p.m. Dr. A. B. Kingsford, "Co-Education during Adolescence."

Chemical, Burlington House, W., 8.30 p.m. 1. Mr. M. Banerjee, "The Action of Allium Sativum or Garlic-Juice on Lead and Mercury." 2. Messrs. E. Goulding and R. G. Pelly, "p-Methoxysalicyl-aldehyde and its Occurrence in the Root of a Species of Chlorocodon." 3. Messrs. A. G. Green and E. A. Bearder, "The Alkaline Condensations of Nitrohydrazo Compounds." Part I. 4. Mr. H. Christopher, "A Simple Piece of Apparatus for Sublimation in Vacuo." 5. Mr. J. B. Firth, "A Note on the Dehydration of Crystals." 6. Mr. F. P. Dunn, "The Diphenylcarbamidoximes." (Preliminary Note.) 7. Messrs. A. Lapworth and V. Steele, (a) "Some Properties of Phenyl Isopropyl Ketone," (b) "A New Stereoisomeride of Cyanodi-hydrocarvone." 8. Mr. V. Steele, "The Action of Hydrogen Cyanide on Carvone Hydrosulphide." 9. Messrs. A. McKenzie and F. Barrow, "Experiments on the Walden Inversion. Part VII.—Action of Phosphorus Pentachloride and of Thionyl Chloride on optically active Hydroxy Acids and Esters." 10. Mr. P. Neogi, "Preparation of the Nitrites of the Primary, Secondary, and Tertiary Amine Bases." 11. Mr. R. E. Slade, "Studies of Ammonium Solutions. Part I.—An Ammonium Electrode."

Mining and Metallurgy, at the Geological Society, Burlington House, Piccadilly, London, W., 8 p.m. Mr. H. S. Ball, "The Economics of Tube-Milling," and Mr. E. Coste, "Fallacies in the Theory of the Organic Origin of Petroleums."

Camera Club, 17, John-street, Adelphi, W.C., 8.30 p.m. Mr. L. H. Piper, "Westminster Abbey."

Friday, October 20...Mechanical Engineers, Storey's-gate, Westminster, S.W., 8 p.m. Messrs. E. M. Eden, W. N. Rose, and F. L. Cunningham, "The Endurance of Metals; Experiments on Rotating Beams at University College, London."

Journal of the Royal Society of Arts.

No. 3,074. VOL. LIX.

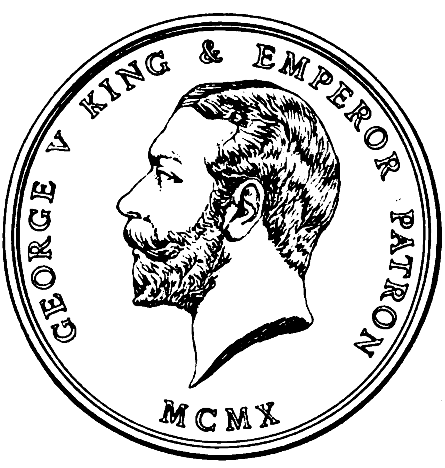
FRIDAY, OCTOBER 20, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

THE SOCIETY'S MEDAL.

It was mentioned in the last Council Report that H.M. King George V., on becoming Patron of the Society, had graciously consented that his head should be engraved on the medal, and had expressed the wish that the work should be carried out by Mr. Bertram Mackennal, A.R.A. The die was prepared from Mr. Mackennal's model by Mr. Allan Wyon, and an illustration of the new medal is now given. This die will



THE SOCIETY'S MEDAL.

be used in future for the Society's medals, including those gained at the examinations held in April last, and those awarded during the past session, which will be presented by the Chairman at the opening of the new session next month. The first medal struck was presented to his Majesty, who has intimated his warm approval of it.

No change has been made in the reverse of the medal.

EXAMINATIONS.

The programme for 1912 is now ready. The price of the programme (containing the previous year's papers and the examiners' reports on the work done) is 3*d.* (post free 4½*d.*). Copies can be had at this price on application to the Secretary, Royal Society of Arts, Adelphi, W.C.

The examinations are arranged under the following stages: — Stage I. — Elementary; Stage II. — Intermediate; Stage III. — Advanced.

The subjects include: — Book-keeping, Accounting and Banking, Shorthand, Type-writing, Economics, Précis-writing, Commercial Law, Commercial History and Geography, Arithmetic, Business Training, Handwriting, and Modern Languages.

The examinations will commence on Monday, March 25th, 1912.

In the Advanced and Intermediate Stages First and Second-class Certificates will be granted in each subject.

In the Elementary Stage Certificates will be given in each of the subjects enumerated. These will be of one class only.

Certificates of proficiency will be granted in each stage to Candidates who pass in certain specified subjects during a given period.

In Rudiments of Music Higher and Elementary Certificates will be given; in Harmony Higher, Intermediate, and Elementary Certificates.

A fee of 2*s.* 6*d.* will be required by the Society from each Candidate in each subject in the Advanced and Intermediate Stages, and in the Elementary Stage a fee of 2*s.* for one subject, and 1*s.* for each additional subject taken up by the same candidate. The fees for Harmony and Rudiments of Music are the same as for Stages II. and III.

Medals and Prizes are offered in each subject in Stages II. and III. Full particulars will be found in the programme.

Examinations are also held in the Practice of Music, and Vivâ Voce Examinations in French, German, Spanish Portuguese, and Italian. For information as to these examinations reference should be made to the programme.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

ROCK CRYSTAL: ITS STRUCTURE AND USES.

By Alfred E. H. Tutton, M.A., D.Sc., F.R.S.

Lecture III.—Delivered May 15th, 1911.

The most important and convincing evidence of the right- and left-handed screw structure of quartz is afforded by the optical properties of the mineral, to which this third lecture will be devoted. In common with all crystals belonging to the trigonal system of symmetry, as well as those of hexagonal and tetragonal symmetry, the three systems which are optically uniaxial, the optical characters are graphically symbolised by an ellipsoid of revolution, the axis of which is the trigonal axis of symmetry, the axis of the prism in the case of quartz. The ellipsoid may be constructed so as to express the value of the refractive index of rays vibrating along any direction within the crystal; that is, the ellipsoid in this case is such that any principal section (a section containing the axis) is an ellipse the major or minor axis of which represents the value of the refractive index ϵ of a ray composed of waves vibrating parallel to the trigonal axis, while the minor or major axis of the ellipse, at right angles to the one just referred to, expresses the refractive index ω of a ray vibrating perpendicularly to the trigonal axis in the circular section of the ellipsoid. Now these two refractive indices, ϵ and ω, are the two extreme values of the refractive index for the whole crystal. Other radii of the ellipse express by their lengths the intermediate values between these two extremes. If this ellipsoid of refractive index be an elongated one, owing to ϵ being greater than ω, the crystal is conventionally termed positive, and this is the case with quartz; if it be oblate, ω being the greater, it is called negative, and calcite is an excellent example of this type of uniaxial crystal. The difference between ϵ and ω is the measure of the amount of the double refraction. This is small in the case of quartz, namely, 0·0091, for $\epsilon = 1·5534$ and $\omega = 1·5443$; but it is very large in the case of calcite, being 0·1719, for $\epsilon = 1·4864$ and $\omega = 1·6583$.

If, therefore, we pass a beam of light along the axis of a quartz crystal or any other uniaxial crystal (the term uniaxial referring to the property, to be subsequently discussed, of a single "optic axis" being exhibited along the singular axis of revolution of the ellipsoid, the axis likewise of trigonal symmetry and of the prism in the case of quartz), the light vibrations, always perpendicular to the direction of propagation, may continue to vibrate in any and every azimuth parallel to the circular section of the ellipsoid, with the same velocity and, therefore, the same refractive index, this latter being the inverse measure of velocity. There is consequently no double refraction experienced by such a beam travelling along the prism-axis of quartz. But if the beam be otherwise directed, double refraction does occur, and to its maximum extent when the beam is sent along the equatorial plane of the crystal, the circular section of the ellipsoid. It is then separated into two distinct rays, one vibrating in the equatorial plane perpendicular to the axis, but at right angles to the direction of propagation of the beam, and another vibrating parallel to the axis. All other rays of intermediate character are eliminated by mutual destruction. These two surviving rays travel with different velocities, inversely proportional to the two refractive indices ω and ϵ.

Indeed, if we cut the crystal in the shape of a 60°-prism, with its refracting edge parallel to the trigonal axis, that of the original crystal-prism, we shall find that the two rays are differently refracted, and that we obtain two spectra, one corresponding to each ray, from the prism, instead of only a single spectrum as given by glass. Moreover, the different amounts by which the two spectra are deviated from the direct line of propagation of the beam afford us the direct measure of the two refractive indices ϵ and ω. For we have only to place the 60°-prism on a spectrometer, and to determine in the ordinary well-known way the minimum amount of deviation suffered by each ray—that is, the minimum deviation of the two images of the collimator slit as seen through the telescope, using monochromatic light of a suitable series of wave-lengths—in order to be able to calculate, with the aid of the additional knowledge of the exact refracting angle of the prism, as measured on the same instrument, the actual values of

the two refractive indices ϵ and ω. We discriminate which image of the slit belongs to the one, vibrating parallel to the refracting edge of the prism and to the trigonal axis, and which corresponds to the other, vibrating in the

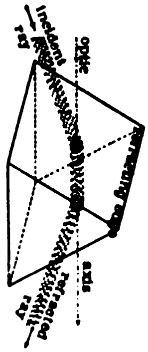


FIG. 21.—60°-PRISM CUT FOR LIGHT TO TRAVERSE AXIS.

perpendicular direction, and in the circular section of the ellipsoid, by means of a Nicol prism; for one image is extinguished when the Nicol is in one position, and the other is quenched when the Nicol is rotated 90°, the known direction of vibration of light transmitted by the Nicol affording us thus the exact knowledge as to which image corresponds to which index.

With these elementary facts before us, we may now investigate the behaviour of quartz. First, we may study the effect of passing the light from the lantern, a slit in front of which is focussed on the screen by a lens, through two 60°-prisms, one cut so that the light passes through the crystal at minimum deviation parallel to the axis, as shown in Fig. 21, and another as just described, with the refracting edge parallel to the trigonal and optic axis, as shown in Fig. 22. In the latter case we see two spectra on the screen, which are separately extinguished by a large Nicol prism placed in the path of the rays, when rotated to two positions 90° apart; while in the former case only a single spectrum is produced on the screen, and remains permanent when the Nicol is placed in position and rotated, just, in fact, as if the quartz prism were made of glass. This is the mode of cutting quartz prisms employed for use in experiments with ultra-violet light, such as the investigation of the ultra-violet spectrum, quartz being remarkably transparent to these ultra-violet rays of short wave-length, which are entirely cut off by glass.

In the case of a quartz prism cut (as shown in Fig. 22), the two spectra are very close together, as the double refraction of quartz is weak, ϵ and ω not being very different (1·5534 and 1·5443). But in the case of calcite, a very strongly doubly refractive mineral, they are far apart, corresponding to the much greater difference between ϵ and ω (1·4864 and 1·6583).

If we examine a prism of a crystal such as fluor-spar or rock-salt, belonging to the cubic system, we obtain only one image of the slit, which is permanent for all positions of the Nicol. For the ellipsoid of revolution of a uniaxial crystal becomes a sphere when the perfect symmetry of the cubic system is reached, the optical properties, and therefore among them the most important of the optical constants the refractive index μ, being alike in every direction in a cubic crystal. On the other hand, if we cut prisms out of a crystal belonging to either the rhombic, monoclinic, or triclinic system—such as gypsum, the hydrated sulphate of lime, $CaSO_4.2H_2O$, the beautifully clear transparent crystals of which are currently known as selenite and which crystallises in the monoclinic system—we find no direction of truly single refraction, but in general obtain two spectra, however the 60°-prism may be cut. As we shall see subsequently, it is true that there are two positions of approximate single refraction, the two "optic axes" from which these crystals are called "biaxial"; but these are fortuitous positions not identical with any axes of the optical ellipsoid, although essentially symmetrical thereto. Any 60°-prism cut for the purpose of determining the refractive indices of gypsum or other biaxial crystal, with its refractive edge parallel to a principal axis of the

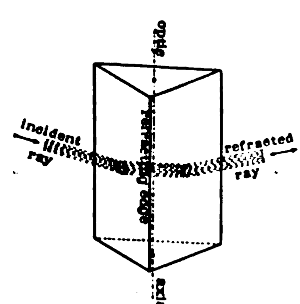

FIG. 22.—60°-PRISM WITH REFRACTING EDGE PARALLEL AXIS.

optical ellipsoid and its bisecting plane parallel to this and to a second principal axis, will always show two spectra, and afford thereby the two different refractive indices corresponding to light waves vibrating along those two rectangular

principal axes of the ellipsoid. Thus the revolution ellipsoid of the uniaxial systems becomes in the biaxial systems one of general form having three unequal rectangular axes, corresponding to three different refractive indices, α the smallest, β an intermediate, and γ the greatest index. The particular prism of gypsum experimented with affords α and γ, the two extreme indices, and their separation being small it is readily perceived that gypsum is not a substance of strong double refraction.

Let us now pass from the study of 60°-prisms to that of plates. A plate of a cubic crystal behaves optically just like glass, but one of either a uniaxial or a biaxial crystal affords highly interesting phenomena of a characteristic nature, which at once enable us to allocate the crystal from which the plate is cut to one of these two great divisions of crystals. The indications are particularly clear and decisive if the beam of light be made convergent, and the light itself be polarised, the Nicols being crossed. For if the plate be cut perpendicularly to the axis of a hexagonal, tetragonal, or trigonal crystal we obtain the well-known concentric spectrum-coloured rings, resembling those of Newton but crossed by a rectangular dark cross, the arms of which mark the directions of vibration of the crossed Nicols, as shown in Fig. 23. If, however, the crystal be rhombic, monoclinic, or triclinic, and the plate be cut perpendicularly to the particular axis of the optical ellipsoid which corresponds to that one of the two extreme refractive indices α and γ which is furthest removed from the intermediate index β, we obtain a figure showing two such ring systems, or "optic eyes," each with its own series of rings as shown in Fig. 24, and the exact positions of which are indicated by the vertices of two dark hyperbolic "brushes" into which the dark cross (one limb of which joins the two optic axes) opens out when the plate, or the pair of Nicols simultaneously, is rotated 45°, the conditions chosen for Fig. 24.

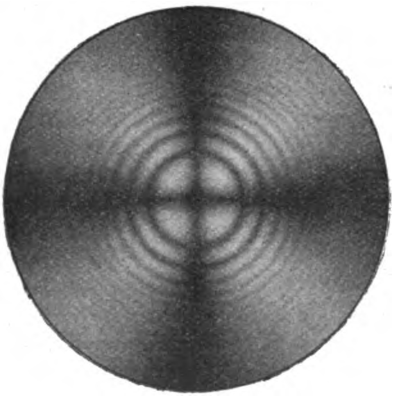

Fig. 23.—Uniaxial Interference Figure.

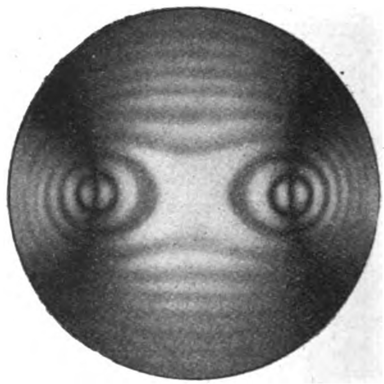

Fig. 24.—Biaxial Interference Figure.

Now we may take calcite and aragonite as two very typical normal cases of uniaxial and biaxial crystals, and show their optic axial figures on the screen with the aid of the projection polariscope. The former affords a very typical uniaxial figure, which remains unaffected on rotation of the plate. Aragonite possesses a small optic axial angle, 30° 52′ for sodium light as seen in air, but only 18° 11′ within the crystal itself. The angle varies somewhat with the wave-length, but not so much in the case of aragonite as in many other well-known cases.

We next proceed to study quartz, the special subject of these lectures, being now armed with the knowledge of the normal phenomena to be expected from a uniaxial crystal. Placing first a thin plate of quartz (one millimetre thick) in the polariscope arranged for convergent light, we perceive a more or less normal uniaxial figure, although the rings are large and diffuse and the dark cross present is also very diffuse, the whole figure wanting the sharpness of that afforded by calcite. If we now take a thicker plate, say one 3·75 millimetres thick, a thickness which is very convenient as will presently be shown, we observe that the coloured rings are more numerous, the innermost being smaller, and the arms of the cross sharper near the margin of the field; but they have entirely disappeared from the centre of the figure, as shown in Fig. 25, and the whole of the interior of the innermost ring is filled instead with yellow light. Moreover, if we rotate the analysing Nicol clockwise we observe that this ring

expands if the plate has been cut from a right-handed crystal of quartz, but contracts if the crystal be a left-handed one, the circular nature of the ring also altering until it is nearly square. If, now, we superpose two such plates 3·75 millimetres thick, one of right-handed quartz and the other of left-handed, we obtain a remarkable change in the figure, namely, the production of the celebrated spirals of Airy, as shown in Fig. 26.*

Now these phenomena at once suggest to us a spiral, and a complementarily helical, arrangement of the atoms composing the chemical molecules of silica in the two forms of quartz crystals. That the supposition is correct may be proved, as first shown by Reusch, by reproducing the effects by means of a spirally arranged pile of biaxial mica films, twenty-four equally thin films of ordinary muscovite mica

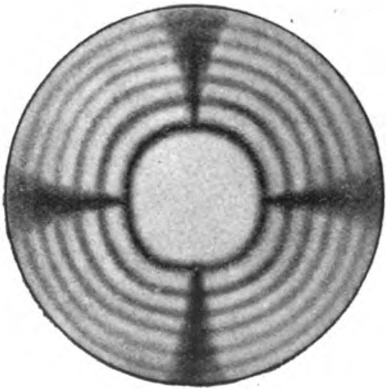

FIG. 25.—QUARTZ FIGURE.

such as can be bought in sheets being adequate. They are laid over each other so that the direction of the line joining the two optic axes of the mica regularly rotates by the same angle, say 60°, which is a very suitable angle of variation. For if the pile be arranged in a right-handed screw, of four turns, six films going to each complete turn, the biaxial figure normally given by muscovite mica, which is shown in Fig. 27, will be found on placing the composite pile in the polariscope to have been converted into a uniaxial one. Moreover, the figure resembles that afforded by quartz to a remarkable degree of precision, for if the pile be a right-handed one the figure is similar to that afforded by right-handed quartz, and gives the same effects on rotating the analyser; whereas, if the pile of mica films had been wound in a left-handed screw the effects produced would resemble those afforded by a plate of left-handed quartz. Further, the proof of the helical structure of quartz is completed by the interesting fact that if we superpose the two piles of mica plates, the left-handed and the

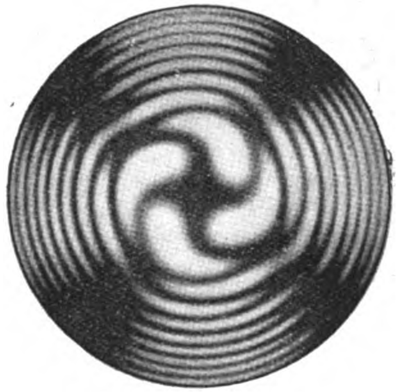

FIG. 26.—AIRY'S SPIRALS.

right-handed, and place them together in the polariscope, Airy's spirals are at once produced on the screen.

Let us now proceed to study quartz plates in a parallel beam of polarised light. If we take two plates, one of right-hand quartz and the other of left-hand, each of 7·5 millimetres thickness, we find that they each give with crossed Nicols the well-known rose-violet tint of passage, between the first and second orders of Newton's spectra. But on rotating the analysing Nicol clockwise the right-handed plate changes colour first to red, then to orange, yellow, green, and blue, while the left-handed plate becomes first blue, then passes through

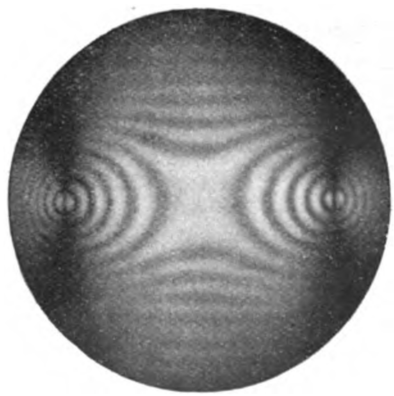

FIG. 27.—MUSCOVITE MICA FIGURE.

green and yellow to orange and red. On the other hand, the two plates of 3·75 millimetres thickness appear yellow under crossed Nicols, just as were the centres of the interference

figures in convergent polarised light, and they change colour in opposite directions of the spectrum on rotating the analyser, until they become violet with the tint of passage when the Nicols are parallel.

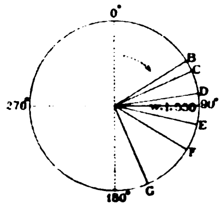

FIG. 28.—ROTATIONS BY 3·75 MM. OF QUARTZ.

Now all these beautiful phenomena are due, as we have already surmised, to the fact that when a beam of light is sent along the axis of a quartz crystal, the right- or left-handed arrangement of the molecules of silica causes the plane of vibration of the polarised light received from the polarising Nicol to be rotated in the same direction, the amount being directly proportional to the thickness of the plate. It also varies considerably with the wave-length of the light. For plates of 3·75 and 7·5 millimetres thickness respectively the rotations by plates one millimetre thick are to the extents indicated in Figs. 28 and 29. It will be obvious from Fig. 28 that the plane of vibration of yellow light of wave-length 0·000550 is rotated just 90° by a plate of 3·75 millimetres thickness, and this fact at once explains the production of the violet tint of passage when we have rotated the analysing Nicol 90°, that is, until it is parallel to the polarising Nicol. For the extinction of this yellow light leaves the complementary colour, the violet transition tint, predominant. And when we double the thickness of the plate to 7·5 millimetres the yellow ray of 0·000550 millimetre wave-length is rotated just 180°, as shown in Fig. 29, which brings the

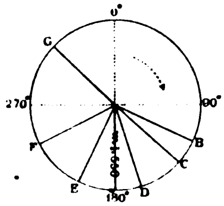

FIG. 29.—ROTATIONS BY 7·5 MM. OF QUARTZ.

Nicols into the crossed position again if we attempt to follow the rotation, and thus the violet transition tint is at once given by such a plate under crossed Nicols, the effect being the same whether we leave the Nicols in their original position of crossing or rotate either of them for 180°.

Several modes of demonstrating the rotation of the plane of polarisation by quartz may profitably be shown. The most striking of them is due to Professor S. P. Thompson. A circular film of mica constructed of twenty-four sectors is used. Each sector is obviously of 15° angle, and the film is so chosen and cut that the angle is bisected by the line joining the two optic axes of the mica crystal. The thickness of the film is such as corresponds to half a wave-length of retardation of one of the two rays produced by the double refraction of the mineral behind the other. The sectors are cemented by balsam between a couple of glass plates in close contact so as to produce a circular disc. On placing the arrangement in the polariscope with crossed

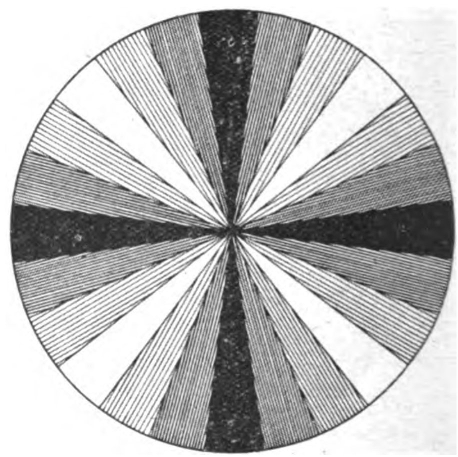

FIG. 30.—PROFESSOR THOMPSON'S MICA SECTORS.

Nicols a black cross is seen on the screen, as shown in Fig. 30, the four sectors, the bisecting lines of which are vertical and horizontal, being in their extinction positions, the two principal rectangular axes of the optical ellipsoid of mica being parallel to the vibration directions of the two Nicols. The sectors at the 45°-diagonal positions are brightly illuminated by colourless light, and the other intermediate sections appear more or less shaded in graduated tints of sepia. On now introducing a plate of quartz one millimetre thick in the path of the beam from the lantern the black cross is rotated one sector to the right or left, according as the plate has been cut from a right-handed or a left-handed crystal or quartz, the jet blackness of the cross being also changed to a deep vandyke-brown.

The colour produced by thick plates of

quartz in polarised light is thus due to optical rotation, and the colour is quite as brilliant as that due to double refraction shown by thin plates of quartz, such as those of rock-sections, which vary from a twenty-fifth to a fiftieth of a millimetre in thickness. The phenomenon of optical activity is confined to crystals belonging to those eleven classes of symmetry which exhibit right- and left-handed forms, that is, in which there is no plane of symmetry developed. Now besides the ordinary right- and left-handed forms, as shown by trigonal quartz and by monoclinic tartaric acid, a most interesting substance from the point of view of the phenomenon in question, chemists have discovered many cases in which the optical activity is either masked, neutralised, or destroyed by intimate lamellar twinning of the two complementary varieties or by chemical combination of the two sets of molecules in which the atoms are oppositely spirally arranged. In the former case of regularly repeated twinning the symmetry is apparently enhanced by the introduction of a plane of symmetry, the composite crystal showing the characteristic faces of both right- and left-handed forms. In the latter case chemical combination results in the production of a new substance, and the crystalline form is altogether different, and may even belong to another system. This is the case with tartaric acid, for the combination of the two sets of molecules produces racemic acid, which crystallises in the triclinic system with a molecule of water of crystallisation, totally unlike the crystals of either ordinary dextro (right-handed) tartaric acid or the complementary lævo (left-handed) tartaric acid, both of which belong to the sphenoidal class of the monoclinic system and are anhydrous. A pair of such complementary crystals of the two varieties of tartaric acid are shown in Fig. 31. Racemic acid is optically inactive, the case being thus one of external compensation, that is, by union of the complementary molecules.

Molecular compounds of this character, however, are often weak, and in the cases of certain salts of racemic acid, ammonium sodium racemate for instance, the product of crystallisation is often found to be a mixture of the two complementary varieties of the testrates, dissociation of the feeble chemical union having occurred.

Besides this production of optical inactivity by the chemical union of the two optical antipodes, that is, by compensation and mutual destruction of optical activity by bodily union from without, and doubling of the molecular constitution, there is another mode of production of an inactive variety possible, by compensation within the molecule itself, whenever there are two groups of atoms surrounding two carbon atoms which can arrange themselves in mirror-image fashion, the two halves of the molecule being thus mutually symmetrical to a symmetry plane. Such occurs in the case of the truly inactive variety of tartaric acid, for this modification of the acid can under no circumstances be split up into two optically active components.

Now the racemic form of optical inactivity, the form produced by external compensation (outside the molecule), is often simulated to a most remarkable extent by the repeated twinning already referred to; but such forms can generally be readily distinguished from truly racemic forms by the crystallographic fact, that whereas a truly racemic form exhibits another and quite distinct crystallographic form, usually belonging to another class or even system of

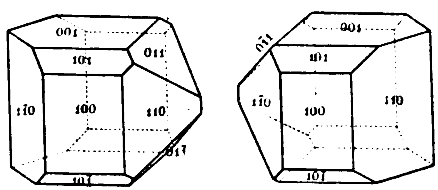

Fig. 31.—The Two Forms of Tartaric Acid.

symmetry, the "pseudo-racemic" form exhibits the symmetry of the same system, although most probably that of a class of higher symmetry in the system, owing to the introduction of a plane of symmetry, about which the twinned individuals are disposed in mirror-image fashion. This case of the mechanical enhancement of the symmetry by repetition twinning is beautifully illustrated by quartz, especially in the exquisite form of the mineral known as amethyst. In order to understand this further extremely interesting lesson to be learnt from rock crystal, we must first study the optical characters of twins of the right-handed and left-handed varieties of quartz; indeed, it will well repay us to consider also as a preliminary two kinds of artificial combinations of the two varieties of quartz.

The first kind of composite quartz, the well-known "biquartz," is, moreover, of great practical value. Two plates of equal thickness are cut and polished out of a right-handed and a left-handed crystal respectively, of either 3·75 or 7·5 millimetres thickness, truly at right angles to the optic and trigonal axis. An edge-

face is ground and polished on each, perpendicular to the plate, and thus truly parallel to the axis, and the two plates are then cemented together by this narrow face, which becomes almost invisible as the cementing Canada balsam has almost the same refractive index (1·548) as

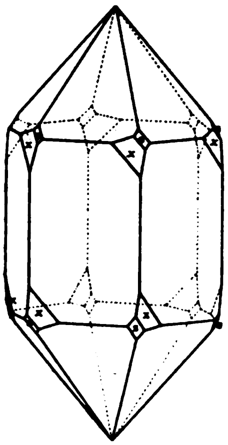

FIG. 32.

quartz, so that the plate appears as a single one. Such a composite plate, under crossed Nicols, if of 7·5 millimetres thickness or under parallel Nicols if half that thickness, exhibits an even transition violet tint, the line of junction being invisible. But the moment the analysing Nicol

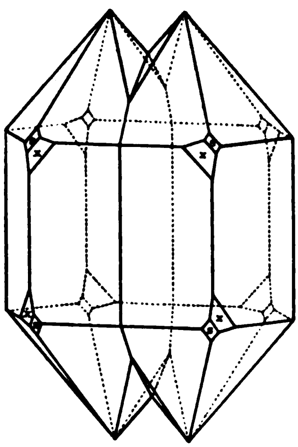

FIG. 33.

is slightly rotated, or another optically active substance or quartz plate is introduced into the path of the rays, difference of colour becomes apparent in the two halves, the biquartz thus acting as a very delicate test either for the adjustment of the Nicols to crossing or parallelism or for optical rotation in another substance. For this latter reason it is much used in saccharimeters, polariscopes for the determination of the optical rotation of sugars and other optically active substances.

The second kind of artificially composite quartz plate is one in which the narrow side-face of junction is made oblique to the plate, being ground say at 45° or 60° to the plate surfaces. The two plates thus similarly bevelled, of respectively right-handed and left-handed quartz, are then cemented together in a mutually inverted manner, so as again to form a continuous plate. When such a plate is examined in the polariscope under crossed Nicols, the area of overlapping is observed to be marked by a black band, and if the angle of obliquity of the junction be as much as 45° a white band will appear on each side of the black one, and outside this again a spectrum band is usually shown,

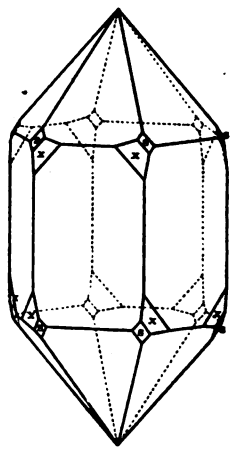

FIG. 34.

the whole elongated strip having the appearance of a ribbon coloured at the margins and black along the central line, with intermediate white strips. The black band marks the line of exact neutralisation of the rotations produced by equal thicknesses of right and left quartz, and the spectra mark the gradual increase of preponderance of thickness of one variety over the other.

Proceeding now to the study of natural quartz twins, it must first be made clear that there are two well-marked kinds of quartz twins, one in which the two individuals are of the same right- or left-handed variety, and another in which a right-handed crystal is twinned with a left-handed one. An example of the former type is shown in Fig. 32, which represents a twin of right-handed quartz, one of the two right-handed crystals of which is situated with respect to the other as if, starting parallel, it had been rotated for 180° about the vertical trigonal axis,

but with complete interpenetration, in the case actually shown, of the one individual within the other. The tangible result is an apparently single crystal, but with the little pyramidal and trapezohedral faces *s* and *x* similarly orientated on every corner, arranged in a right-handed manner, instead of on alternate quoins only.

The other kind of quartz twin, frequently found occurring among specimens from Brazil, is represented in Fig. 33 by a case of partial interpenetration, and in Fig. 34 by an example in which complete interpenetration has occurred. The plan of the twinning is that the twin plane is a face of the hexagonal prism of the second order, perpendicular to a pair of the faces of the hexagonal prism present, which is of the first order. When interpenetration is complete, as in Fig. 34, the little *s* and *x* faces are shown on every corner, but symmetrically, as if the crystal were of holohedral symmetry.

Now, if a section-plate of such a crystal be cut, of 3·75 or 7·5 millimetres thickness, perpendicularly to the axis, the polarisation phenomena, due to the opposite optical activity of the two different varieties present, will vary according to the mode of internal disposition of the parts composed of the two varieties, right- and left-handed. When the whole of one half of the crystal is of right-handed and the other of left-handed quartz, and the surface of junction is a plane parallel to the axis, we have a natural biquartz produced on cutting such a section-plate, which shows absolutely no trace of a junction-plane in ordinary light or when the Nicols are crossed or parallel, but which exhibits different colours in the two halves the moment either Nicol is rotated to even the slightest extent. Two such natural biquartzes are exhibited on the screen. They are excellent examples, obtained after long searching.

If the plane of junction be oblique, however, the biquartz shows a black band between the two halves when the Nicols are crossed, and a white one when they are parallel, as is the case with the natural biquartz next projected on the screen, the obliquity of the junction plane not being great in this example. A third natural biquartz, with a junction-plane of greater obliquity, next exhibited, shows not only the central black band but a white one and a spectrum on each side of it, very like the artificial specimen already referred to and illustrated on the screen.

A very instructive case is that of a natural quartz twin-combination, which by its picture on the screen in polarised light is seen to be composed of one half of left-handed quartz, which polarises in a rich crimson lake with crossed Nicols, and a second half which is made up of alternating right- and left-handed quartz, the strips being joined obliquely to the plate, so that a black band is produced in each case as the central line of a ribbon, being flanked by a white band and a spectrum band on each side. A faint idea of this screen picture may be gathered from Fig. 35.

Now, such a banded structure of alternately right- and left-handed quartz affords an instance on a larger scale of the finely-laminated twinning of the two varieties present in amethyst. Several further examples of ribbon-band structure may first be referred to, however, such as a particularly fine one in which the ribbons form the boundaries of V-shaped

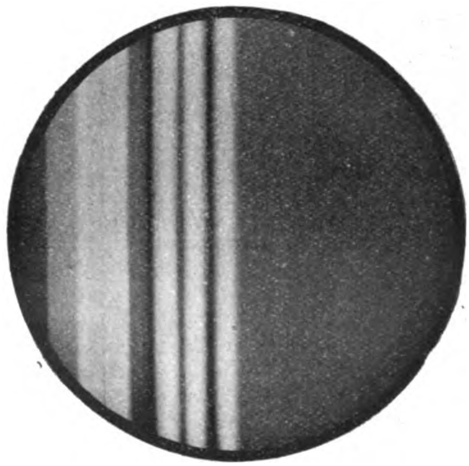

FIG. 35.—BANDED QUARTZ TWINNING.

intrusions, of 60° or 120° angle, of one variety in a crystal of the other variety. Also many very beautiful cases of irregular composition occur, such as the cases next projected on the screen, one of which gives a polarisation effect like snow mountains with green bases, intruding upwards into a blue sky, reminding one of many a glorious Alpine expedition.

The case of amethyst is an exceedingly beautiful and highly instructive one. A plan of the effect seen on the screen with a typical section perpendicular to the axis of an amethyst crystal is shown in Fig. 36. The marginal parts show polarisation colours in three sectors, *x*, *y*, *z*, indicating the presence of right- or left-handed quartz, *y* being left- and *z* right-handed; *x*, however, is composite, the upper part, x_r, being right-handed and the lower part, x_l, left-handed, and where the two join there is overlapping, and

a ribbon band, x_{rl}, with black line in the middle, is produced. The convergent light phenomena correspond, z and x_r giving a right-handed uniaxial figure and y and x_l a left-handed interference figure, while x_{rl} affords Airy's spirals. The alternate sectors A, B, C, however, show no definite polarisation-colour phenomena, except the natural violet colour which is characteristic of these alternate sectors and is the distinctive feature of most amethysts: hence the name. But in the central halves these sectors exhibit the beautiful laminated twinning effect, under crossed Nicols a delicate slate-coloured line marking the junction of each pair of right and left laminæ, each lamina itself appearing as a thin white band between the slate defining line shaded by traces of spectra. On rotating the analysing Nicol the laminæ exhibit the most

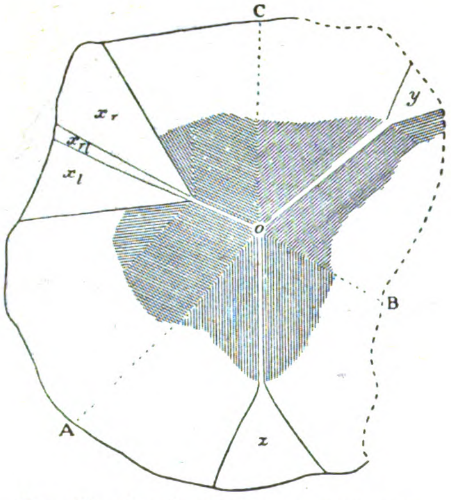

FIG. 36.—THE STRUCTURE OF AMETHYST.

beautiful shades of grays and browns, with delicate linings of rose and other tints. This central part of the plate, moreover, is unique among quartz crystals in exhibiting a uniaxial interference figure in convergent polarised light of the normal kind—that is, with the black cross complete to the centre, just as is afforded by calcite or other non-rotating normal trigonal, hexagonal, or tetragonal crystal.

Thus the intimate lamellar twinning of the two varieties of quartz in amethyst obviously results in the production of a crystal which simulates holohedral trigonal symmetry, the lower-class symmetry in which one variety is the mirror-image of the other being apparently enhanced, so that the one individual crystal itself displays mirror-image symmetry—that is, the presence of a symmetry plane—and the corresponding optical activity of the lower-class pair of varieties is neutralised by their intimate blending. Amethyst, therefore, is not a case of true optical inactivity, but of mechanically and naturally produced pseudo-inactivity. It is thus an excellent illustration on a large scale of the still more intimate blending of microscopic or even submicroscopic laminæ of the two varieties in the organic substances known to chemists as pseudo-racemic compounds, a large number of which have been studied by Kipping and Pope. In many of these cases the blending of the two varieties by regular intercalation and alternation of the two varieties, one within the other, is so intimate that the laminæ approach the molecular dimensions in thinness. It is easy to see that if the approach be continued until this fascinating region of molecular forces is penetrated—for we know that within four or five molecular diameters these intermolecular forces come into play—it is more than likely that some sort of molecular chemical affinity will develop, with the possible production of a molecular compound—a racemic compound—of the two hitherto alternating varieties, the individuality of each variety being no longer preserved, but a new compound, due to the new double molecule, being produced and crystallographically developed according to its own new crystalline form. Thus both the pseudo-racemic form, of which quartz affords us a gross but excellent example, and the true racemic form, are produced by external compensation of the two different molecules mutually by each other; but whereas in the true racemic compound this occurs within the range of action of the molecular forces, in the case of the formation of a pseudo-racemic substance the intimate intercalation occurs outside the effective range of molecular action capable of producing chemical union. An example of such intimate blending by repetition twinning of the ultra-microscopic order is afforded us by potassium chlorate crystals, which are often twinned in layers of such extreme tenuity, not more than the thousandth of a millimetre in thickness, that the crystal faces yield magnificent colours by reflected light alone, without any necessity for the use of polarised light. The reason for this display of the colours of thin films by such crystals has been fully explained by Stokes and Lord Rayleigh, and the most striking result of their investigations, and that of other workers on such substances, has been to show the wonderful equality of thickness of the layers, the two alternating individuals

balancing one another perfectly. So it undoubtedly is in the cases of pseudo-racemic substances, the layers of the two (right- and left-handed) varieties being so truly equal in thickness that the net result is the balanced display of holohedral symmetry instead of the one-sided lower-class symmetry of the system.

In enabling us to grasp this remarkable advance in our knowledge, both of these interesting cases of crystalline structure and of the intricate chemical properties and relationships of optically active substances, quartz has indeed shown itself as the most instructive and uniquely interesting of all the crystallised substances of the natural mineral world.

THE FRENCH PRESERVED FRUIT INDUSTRY.

For a great many years a particularly favoured corner of Provence—the commercial centre of which, so far as the production of preserved fruits is concerned, is Apt—has furnished the choicest preserved, or in popular parlance "candied," fruits, which reach either the European or American markets. In spite of a high rate of customs duty and an abundance of American fruit, these special products have found a ready sale in the most expensive establishments in the United States. The fruit preservers in Apt and in Marseilles have also shipped to America large quantities of cherries simply preserved in brine, which thus escape the high duty applied to fruits preserved in sugar and arrive in proper condition to absorb various liquors, and then to be sold as "Maraschino cherries," and probably under other descriptions. The terms under which the French fruits are sold have passed into the English language. The trade understands the meaning of the words "fruits confits" and "fruits glacés." The former are fruits which retain their natural form and colour and have absorbed quantities of sugar; the latter only differ from the former in that they have been re-dipped and given a crystalline coating of sugar, so that they are dry to the touch and agreeable to handle. The American Consul at Marseilles says that in connection with the preserving process, healthy fruit is selected which is gathered before its maturity, so as to be able to resist the succeeding operations. The first step is to soften the flesh so that it may absorb the sugar, and particular attention is paid in the case of fruit like the pear, walnut or quince, the pellicle of which is removed before the process begins, lest the white flesh thus exposed should become rusty in appearance. To avoid this, fruits of this kind, from which the skin and defective parts have been removed, should be thrown into fresh water that has been slightly acidulated with lime-juice or concentrated vinegar, or, better still, with alum. The pared fruit should not be touched with the hands, but with a long pin, and should be held in this preliminary bath only long enough for the preparation of a sufficient quantity to begin the softening operation. The next important step is to soften the fruit through and through, so that it will absorb the sugar readily. Alum water is recommended for this purpose, and in such quantity that none need be added later after evaporation has reduced the original quantity. With pears, they should "swim well" in a double-bottomed vessel, steam heat preferably being employed. An experienced workman knows, by gently passing the fruit between his fingers, whether or not it is soft through and through. If it is boiled too much it becomes a sort of marmalade, if not enough it will not absorb the sugar. Properly softened, the contents of the boiler are placed in fresh water, which is changed until they become perfectly cool. Pears may be heated until flexible and tender and then pared, or may be pared and then softened. Fruits containing pits, like peaches or cherries, are placed in cold water, over a slow fire, and as they rise in the water they are removed, tested to ascertain whether they are soft enough, and then thrown into cold water. Quinces are cut into four, five, or six pieces before being softened. For Reine Claude plums (greengages), fruit without yellowish rusty spots is selected. They are pricked on every side to the pit, and when softened by heating in plain water, the vessel is removed from the fire and a handful of salt and plenty of vinegar are added. One hour later they are replaced on the fire and well heated. When they come to the surface the fire is quickened, and when all have risen the vessel is removed and the contents are placed in fresh water. The salt and vinegar tend to give back their natural green colour. In the preparation of apricots and peaches, these are wiped with a cloth, then pricked, particularly in the unripened parts, and heated on a slow fire. As they rise and are found soft enough they are thrown into cold water. Fruit having first been softened must next be saturated with sugar. The material is first plunged into a weak syrup, which is concentrated gradually, with one day's interval between the degrees of concentration, according to the heat of the place where the operation is effected. It is sometimes necessary to have an interval of not more than twelve hours during the first few days, lest fermentation sets in. This is what is called to give the fruit a "façon." To give it a "frémie" means to put the material in its syrup upon the fire and leave it until the sugar approaches the boiling-point, in the meantime agitating the vessel occasionally. According to their nature, fruits are treated differently. Fruits with pits must be placed in thin syrup and receive a frémie before two days, after which they are cooked until the sugar has had time to penetrate everywhere. To prevent certain fruits from candying, and particularly such as are charged with gum, a little glucose is added to the last façon. With firm green fruits, the operation begins with a syrup of twenty-five degrees. The material receives from six to eight façons, the syrup being

strengthened each time by two degrees, and the last façon being made with a syrup of thirty-six degrees. Ripe and tender fruit is given a first façon in twenty-eight degree syrup, and is finished in a syrup of thirty-eight degrees. Only one façon per day must be undertaken, unless, under special circumstances (to prevent fermentation), two become necessary. Then it requires six days to complete the process. An ordinary façon lasts five minutes, during which the vessel is shaken occasionally. This period ended, the fruit is drained thoroughly, and the syrup being first skimmed is concentrated by two degrees and again poured over the material. When the last façon takes place care must be taken to allow the fruit to drain, after which it is allowed to rest for fifteen days. To obtain first-class preserved fruit the syrup should be changed after the fourth or fifth façon. If it becomes troubled, the beaten white of egg is added in a little water. No more syrup is employed at a time than is necessary to cover completely the contents of the vessel, as it seems to penetrate more readily. The "fruits glacés" are so prepared as to make them dry, agreeable to the eye, and easy to eat. To accomplish this, the "fruits confits" are drained and slightly washed with tepid water to remove the syrup remaining on their surface. Next, to "glacer" them, sugar is cooked until it bubbles. Into this liquid the fruit is dipped, removed, coated with sugar, and then placed on a wire netting. The glaçage should be thin and light like a varnish, it should bring the colour out and not hide it. Finally, the glaçage should be made at the last moment possible, as fruits are better preserved in syrup. As soon as fruits glacés are dry they are packed in boxes. The Consul states that he has not mentioned the dyeing processes, for the sufficient reason that fruit packers say no more about them than necessary. These processes are, however, said to be perfectly harmless. They certainly enable the packer to present a most attractive article. The delicious "marrons glacés" are not exported from France to far distant countries in any great quantities, on account of the difficulties of transportation. Neither are the dates stuffed with pistache cream, nor the "marrons fondés." Marseilles has always been famous for its fruits and bonbons, a generous rivalry prevailing between a number of the local makers of these articles to produce annually something new and interesting.

HOME INDUSTRIES.

The Cotton Trade Dispute.—It was almost incredible that there should be serious danger of a lock-out in the cotton industry, which might have affected some 200,000 workers, because four non-unionists were employed at the Yatefield Mill and twenty-eight union spinners objected, but none the less there was such danger. Happily a dispute which threatened to develop over the whole area of north and north-east Lancashire has been settled by the four non-unionists joining the spinners' organisation. The operative spinners of Lancashire are very strongly organised, and they look askance at men who, while they reap all the advantages gained by the influence of a trade union, refuse to pay the small weekly subscription to the union funds, and of late the policy of boycotting the non-unionists has been put into practice. The union men have won on this occasion, and they expect to win at other places where the same conditions exist.

Cotton Weavers.—Just now there seems to be a considerable shortage of cotton weavers. In several towns the lack of weavers has made it impossible to put in operation all the looms that have been either wholly or partially stopped during the depression of the last two or three years. Manufacturers in south Lancashire are offering to pay learners who will take up the work. In north and north-east Lancashire cotton-weaving has become so brisk that instances are cited in which girls of seventeen are entrusted with five looms, and are earning from 25*s*. to 28*s*. per week, whilst lads of fourteen are being put in charge of two looms. And it is likely that the lack of labour will be felt even more keenly in the immediate future, for new mills are being erected and old mills re-started, but it is probable that the shortage of labour will disappear when it becomes known that the improvement in trade is likely to be permanent. When trade is slack many operatives leave the manufacturing districts, and do not return until they can rely upon getting regular and remunerative work at the mills again.

The Single Payment Policy.—No one will question the immense benefits conferred upon the community by life assurance, but unfortunately these benefits depend very largely upon the assured retaining health and employment. A man takes out a policy and pays the premium upon it for many years, then illness, or loss of work, makes it impossible for him to continue paying, and he either allows it to lapse, or, if there is a surrender value, has to take less than a third of the actual money he has paid over to the company. In industrial assurance there is, as a rule, no surrender value, and all he can get (and he can only get that after he has been paying premiums for years) is a free policy for a small sum payable at death. Here is the weak point in insurance, and great numbers of the industrial poor suffer from it. For this reason the new departure made by the City Life Assurance Company should be welcomed. This company is now issuing what it calls "The Ideal Single Payment Policy," which gives whole life assurance for a single payment of £5. After the first payment nothing further is payable. The company keeps the policy in force, and in the event of the death of the policy-holder the company pays the full amount stated in the policy. Thus a young man of, say, twenty-one,

with an odd £5 to spare, takes out one of these policies, which assures him the sum of £15 at death. He has no further liability, and if next year he has another £5 to spare he can take out another policy assuring £14 14*s*., and so on from year to year. Or take a young woman of twenty-one. If she takes out one of these policies every year for ten years, she will have over £139 whole life assurance bought at a cost of only £50. The merit of the scheme is that the assured is guarded from loss through the mischances of life. He has paid his money once for all, and, come what may, the benefits of the policy remain to him. It will be surprising if this policy does not become very popular.

Railless Electric Cars.—The report of the deputation recently sent by the Edinburgh Corporation to inspect the railless electric cars of Leeds and Bradford, gives some interesting information respecting capital outlay and operating charges. In both towns the cars cost £700 each. At Leeds the capital outlay, which is mainly on overhead equipment, amounted to £1,246 per mile, and at Bradford to £1,734 per mile. The total operating costs, exclusive of interest and depreciation on capital outlay, in each case amount to 5½*d*. per car mile. The revenue, of course, depends largely upon the route, but at Leeds it amounts to about 8¾*d*. per car mile.

Oil Engines on Railways.—Last year the locomotive engineer of the North British Railway Company designed an electric locomotive with a steam turbine driving a dynamo, which in turn supplied electrical energy to electric motors, and now a leading British railway company has given instructions for the preparation of designs for a 500 h.-p. locomotive of a similar character, but using a Diesel engine for driving the dynamo instead of a steam engine. Commenting upon this new departure, a well-informed correspondent of the *Manchester Guardian* says that the results with the North British type of electric locomotive have not come up to expectations in the matter of economical working, owing to certain causes which were regarded as more or less likely when the experiment was embarked upon. The use of the Diesel engine, it is believed, will remove these difficulties, and at the same time reduce the size and weight of the locomotive, factors which will be of considerable importance in relation to the effect of such a type of engine upon existing permanent way, and also in the facility for negotiating curves at speed. If it can be demonstrated that the application of the internal-combustion engine for main line working is possible, a marked step in advance will have been made, as this method would not require any alteration of existing tracks or of telephonic or telegraphic local circuits, and would mean a considerable decrease in fuel, haulage costs, and water supply.

The Tonnage of Liners.—The growth in the dimensions of liners continues, and it looks as if Lord Pirrie's prediction that we shall see 1,000-feet ships will soon be realised. The Cunarder now being built at Clydebank is to have a length over all of 905 feet, which is 100 feet longer than the "Lusitania," and 20 feet more than the "Olympic." But the German "Imperator," now in course of construction in Germany for the Hamburg-America line, will have a length of 910 feet, with a tonnage of 50,000. Nor is it only steamers intended for the New York service that are growing in size. The new Allan steamers will be larger than the "Laurentic" and "Megantic," while the two liners being built for the Canadian Pacific Company's Vancouver-Hong Kong route will be larger in every respect than the company's well-known St. Lawrence "Empresses." But there is no similar advance in speed.

Domestic Service.—A committee has been appointed by the Women's Industrial Council with the object of improving domestic service as a career for industrial women. As a first step the committee will institute a widespread inquiry into existing conditions. A somewhat similar investigation was made about ten years ago, and the results were published by Miss Catherine Webb in the *Nineteenth Century* for June 1908, but little came of it. The conditions of domestic service are pretty well known, and the reasons why it is disliked. The reforms which are about to be suggested are in three directions: (1) Towards greater efficiency on the part of the employed; (2) towards their organisation and co-operation; (3) towards improved material conditions of service. No. 1 is desirable, but will hardly make the service more popular. No. 2 will be difficult to bring about. Something may be done in the direction of No. 3. There are many difficulties to be confronted. There is the notion among the artisan class that a girl who enters domestic service loses caste; there is the continuous service as contrasted with the comparative freedom of the outside worker, and there is the objection of the parents that the girl would earn more in, say, a factory, and that domestic service "doesn't put a trade into her hands when she marries." But nothing would be done in the way of social reform if the contemplation of difficulties prevented efforts at amelioration, and those who are tempted to question the possibility of raising the status of the domestic servant may profitably remember what has been done in that direction on behalf of the sick nurse.

CORRESPONDENCE.

DEW-PONDS.

The unusually dry summer which has just come to an end has afforded an excellent opportunity of testing the tradition that "dew-ponds" derive

their supply of water mainly from dew or mist, and never go dry.

Having taken a great interest in the investigations which have been in progress during the last three years, and the discussion in this *Journal* and other similar publications, I was curious to know how the ponds had fared. I wrote accordingly to the Royal Engineer officers under whose charge is that part of Salisbury Plain which is War Department property, to inquire. The report received states that "all dew-ponds in the Plain have gone absolutely dry this summer without exception."

The officer who kindly supplied this information adds that the ponds are generally, but not always, placed where they will take surface drainage, and consequently they received no doubt a certain amount of what little rainfall there has been. Perhaps some member of the Society who has had opportunities of observing the dew-ponds on the South Downs will be good enough to say what their case is.

WM. PITT (Colonel).

Enham House, Andover.

SLAG AND FURNACE REFUSE ORNAMENTS.

I notice in your correspondence a query by Mr. Ryle as to the glass ornaments made from slag. These were made when pressed glass first came in. The Gateshead Glass Works at Gateshead-on-Tyne is where they were made, and the owner of the works at the time, Mr. J. G. Sowerby, a perfect artist by intuition, made this and various other forms of glass-ware. His special Gateshead Art Glass was very much admired, and was really unique, until the German makers copied it badly and vulgarised most of it by careless repetition.

His artistic effects of colour were, however, obtained at a great sacrifice to the ordinary work, and many pots of metal (molten glass) were spoiled by endeavouring to get new effects of colour, etc. It was an interesting piece of work and very artistic, but had to be abandoned, like all truly artistic enterprises in this country—de Morgan tiles being another painful instance of insufficient appreciation.

E. E. PITHER.

Hampstead,
October 16th, 1911.

OBITUARY.

SIR WILLIAM JOHN CROSSLEY, BART.—Sir W. J. Crossley died on the 12th inst. at Manchester, after an operation. Born at Glenburn, in Ulster, in 1844, he was educated at the Royal School, Dungannon, and at Bonn. He entered the machine works of Sir W. G. Armstrong & Co., at Elswick, but at the age of twenty-three he set up, with his brother, the engineering firm Messrs. Crossley Bros., Ltd., in Manchester. They soon made a reputation as gas-engine manufacturers. In 1885 they won a gold medal offered under the Howard Trust by the Society of Arts at the International Inventions Exhibition for the "Otto" gas-engine, and in 1889 they were awarded another gold medal by the Society for a nine horse-power nominal "Otto" gas-engine.

Sir William Crossley found time for much public work. He became President of the Manchester Young Men's Christian Association, treasurer of the United Kingdom Alliance, chairman of the Manchester Hospital for Consumption and Diseases of the Throat, a member of the Cheshire County Council, and a Justice of the Peace for Manchester and Cheshire. He was one of the original promoters of the Manchester Ship Canal, of which he was elected a director.

As the Liberal candidate for the Altrincham Division at the General Election in 1906 he defeated Mr. Coningsby Disraeli, who had held the seat for thirteen years. In January 1910 he was again returned, but in the following December he was defeated by Mr. Kebty-Fletcher.

Sir William Crossley was much interested in the crusade against consumption, and he built and furnished at his own expense a sanatorium in Delamere Forest, Cheshire, for the use of patients from Lancashire towns. On this scheme he spent £70,000. In 1903 Manchester conferred upon him the freedom of the city in recognition of his public services, and in 1909 he was created a baronet.

He joined the Royal Society of Arts in 1884.

NOTES ON BOOKS.

THE PANAMA CANAL. By Harmodio Arias, B.A., LL.B. London: P. S. King & Son. 10*s*. 6*d*. net.

This volume, which forms No. 25 in the excellent series of monographs by writers connected with the London School of Economics and Political Science, is, as its sub-title states, a study in international law and diplomacy, and is an attempt to define the position of the Panama Canal under the law of nations. Mr. Arias has made a careful examination of the history of oceanic transit; he has traced the attitude of the United States of America towards the Canal question, and the variations that it has undergone in the course of years; he has discussed the later amplifications of President Monroe's message, "thus reviewing the diplomatic wrangles that have resulted from the attempt of the United States to apply to this question their famous doctrine in its advanced form"; and he has compared in an instructive way the legal positions of the Suez and Panama Canals. A useful appendix contains the different articles of the Clayton-Bulwer, Hay-Pauncefote and other treaties that bear directly on the matter.

The book is valuable because the expected opening of the Canal in 1915 will shortly make the

subject with which it deals of vital importance to most of the countries of the world. It is written in a clear and scholarly style, and gives a lucid account of an intricate and difficult problem.

THE TEN REPUBLICS. By Robert P. Porter. London: George Routledge & Sons, Ltd. 2*s*. 6*d*. net.

This little work is designed to serve as an introduction to a series of volumes on the Ten Republics of South America, and its appearance is opportune at a time when the commercial importance of these states is becoming every year more and more obvious. During the last ten years the trade of Latin America has increased by nearly £250,000,000, and its annual value is now estimated at £425,000,000. The United Kingdom can claim nearly one-third of the trade of the ten republics, so that their importance as a field for British capital can hardly be over-estimated. There seems little doubt, too, that this trade is capable of almost indefinite expansion, and that such expansion is bound to ensue as soon as the present difficulty—lack of means of communication—is done away with. On every quarter this appears to be the one bar to development. Brazil, for instance, in the first ten months of 1910, exported 31,494 tons of rubber, valued at over twenty-one million pounds; but, large as this amount is, it represents but an insignificant fraction of what might be obtained were it possible to get the rubber down to the coast from the inaccessible tracts in the upper valley of the Amazon. In the state of Minas Geraes, again, it is said that the iron ores form mountains rather than seams, but under present conditions this source of wealth is left practically untouched. Paraguay—to take a further instance—has some of the richest pasture and arable land in the world, but at present the cattle have to be driven such a distance that they are worn out before they reach a market; while the corn, which has to be carried in antiquated bullock-waggons, is rendered comparatively valueless by the cost and difficulty of transport.

Mr. Porter writes with a wide and accurate knowledge of South America, over the greater part of which he has travelled, and he is firmly convinced that, given increased railway communication, an enormous increase in the prosperity of the country may be confidently expected.

PAPERS ON INTER-RACIAL PROBLEMS. Edited by G. Spiller. London: P. S. King & Son. 7*s*. 6*d*. net.

This volume consists of the papers communicated to the first Universal Races Congress, which was held at the University of London last July, and they have been edited for the Congress executive by Mr. G. Spiller, the honorary organiser of the Congress. Many of the papers were reported at considerable length in the daily press at the time of their delivery, but it is extremely interesting to have them gathered together in one imposing volume. The papers are over fifty in number. They were all written with a view to encouraging between the white and coloured peoples "a fuller understanding, the most friendly feelings, and a heartier co-operation." The writers are of many nationalities and of all shades of complexion, but there is a strong similarity in their sentiments and in their ardent desire for the cause of peace and the welfare of the human race as a whole.

Many of the papers, such as Mr. Israel Zangwill's "The Jewish Race," the late Sir Charles Dilke's "Indentured and Forced Labour," Dr. W. E. B. Dubois' "The Negro Race in the United States of America," and the account of the North American Indians by one of them, Dr. Charles A. Eastman, are of great interest; indeed, the only fault one has to find with them is that, owing, no doubt, to the exigencies of the Congress, they are too short. Regarded as a whole, the book is remarkable, and its appearance should be welcome not only on account of the intrinsic value of most of the articles, but also on account of all that the volume symbolises.

GENERAL NOTES.

MEDICAL PRACTITIONERS IN GERMANY.—In 1910 the number of medical men practising in Germany amounted to 32,449, or five doctors for each 10,000 of the population, an increase of 480 over 1909. A still further growth may be expected, the number of medical students having risen from 9,239 in 1909 to 11,125 in 1910. The increase in the number of medical men was mostly in the cities—of the 480 additions, 329 went thereto. For every 10,000 inhabitants Berlin has 12 doctors, Wiesbaden 22, Munich 16, Stuttgart 10, Dresden 9, Leipzig 8, Chemnitz 5, Plauen 5, and Gelsenkirchen 4. The number of female doctors has risen from 55 in 1908 and 69 in 1909, to 102 in 1910. Of these Berlin has 32, Munich 6, Frankfort 6, Dresden 6, and Hamburg 4. The number of female medical students has risen from 371 to 512.

SWINEY LECTURES ON GEOLOGY.—A course of twelve lectures, on "The Natural History of Rocks," will be delivered by T. J. Jehu, M.A., M.D., F.R.S.E., in the Lecture Theatre of the Victoria and Albert Museum, South Kensington (by permission of the Board of Education), on Mondays and Tuesdays at 5 p.m., and Saturdays at 3 p.m., beginning Saturday, November 4th.

MEMORIAL TABLETS. — The London County Council have affixed a memorial tablet to No. 37, Chesham Place. This house was built by Lord John Russell, and occupied by him, with a few breaks, from 1841 to 1870, by far the most important period of his life. A tablet has also been affixed to No. 5, Great Stanhope Street, the residence for some twenty years of Lord Fitzroy

Somerset, Baron Raglan. It was from here that he set forth, in 1854, to take command of the British forces in the Crimea—an expedition from which he was never to return.

THE TURKISH TOBACCO INDUSTRY.—From various centres have come most favourable reports of the Turkish tobacco crop in 1910, which is said to be highly satisfactory. The exports to Europe and America in the fiscal year 1908-9 amounted to 58,000,000 pounds, and in 1909-10 to 70,000,000 pounds. These figures do not include the crop of 1910, or the exports to Egypt, which latter amount to about 8,000,000 pounds a year. There are indications that the present tobacco monopoly, whose thirty-years' concession expires in 1914, will not obtain a renewal of its contract with the Government, as the tobacco planters are vigorously protesting against the Régie's policy of restricting the production. The tobacco grown in and around Xanthi commands the highest price, that of Cavalla comes next, then follow those of Samsoun and Smyrna. In the district of Latakia, on the Syrian coast, is produced the unique product known to commerce as "Latakia tobacco."

THE ORIENTAL CARPET INDUSTRY.—The world's increasing demand for Oriental carpets has caused certain changes in the rug industry, particularly tending towards an enlarged output through the intervention of merchants in Constantinople and Smyrna, who are establishing factories of Persian carpets in both Turkey and Persia. Another new feature of the rug trade is the growing practice, on the part of merchants in Constantinople, of shipping direct—certainly to the United States—from Persia instead of from Constantinople. On the whole, Constantinople maintains its position as the world's principal rug market. Germany buys Oriental carpets in ever-increasing quantities in order to satisfy her own requirements, and those of Scandinavia, South America and Canada. Hamburg, being a free port, is becoming an important distributing centre for Oriental rugs. It is estimated that £1,718,000 worth of Caucasian and Persian rugs are shipped in a year from Constantinople and Smyrna, more than half of which go to Hamburg.

THE ECONOMIC CONDITION OF GERMANY.—An article on the economic, financial, and industrial condition of Germany at the present time, which has appeared recently in *Le Journal* of Paris, gives some interesting figures to prove that the country is in a far more prosperous condition than the majority of people in France suppose. The writer, who bases his assertion on data published in the *Statistiches Jahrbuch*, says, in the first place, that the population of the German Empire has increased during the last thirty years from forty-five millions in 1880 to sixty-five millions in 1910. The production of coal has increased from 53,471 tons in 1880 to 834,000 tons in 1909; iron and steel from 1,548,000 tons to 7,373,000 tons during the same period; the number of workmen from 7,431,000 to 11,348,000. The exports and imports, which amounted in value to 5,712 million of marks (£285,600,000) in 1880, now exceed the sum of 15,000 million marks (£750,000,000) annually. Thirty years ago 46,000 vessels, of an aggregate tonnage of seven millions, entered the German ports; they now number no fewer than 95,322, of 25,418,000 tons. The number of German-owned steamers has increased from 414 to 1,950, and their total tonnage from 216,000 to 2,350,000 tons. The gross receipts of the German railways, which in 1880 were 886 million of marks (£44,300,000), amounted in 1908 to 2,420 million of marks (£121,000,000). In 1880 the total amount deposited at the savings banks throughout the country was 2,614 million of marks (£130,700,000), which had increased in 1910 to 61,053 million marks (£3,052,650,000). The amount of the deposits at other banks all over the country has increased in a similar proportion.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, OCTOBER 23...Farmers' Club, Whitehall Rooms, Whitehall-place, S.W., 4 p.m. Mr. C. Kains-Jackson, "The Metric System as applied to Agriculture."

Sanitary Engineers, Caxton Hall, Westminster, S.W., 7.30 p.m. Mr. Percival M. Fraser, "The Parliamentary Bill on 'Sewers and Drains.'"

East India Association, Caxton Hall, Westminster, S.W., 4 p.m. Mr. Oliver Bainbridge, "Some Anglo-American Impressions of India."

TUESDAY, OCTOBER 24...Zoological, Regent's Park, N.W., 8.30 p.m. 1. Mr. Edward G. Boulenger, "On a new Tree-Frog from Trinidad, living in the Society's Gardens." 2. Mr. Bruce F. Cummings, "Distant Orientation in Amphibia." 3. Mr. Oldfield Thomas, "The Duke of Bedford's Zoological Exploration of Eastern Asia.—XV. On Mammals from the Provinces of Sze-chwan and Yunnan, Western China." 4. Mr. E. P. Stebbing, "Game Sanctuaries and Game Protection in India."

WEDNESDAY, OCTOBER 25...United Service Institution, Whitehall, S.W., 3 p.m. Captain E. Rason, "History of the Communications between Russia and England."

Royal Society of Literature, 20, Hanover-square, W., 5 p.m. Professor R. P. Cowl, "Some Aspects of the XVIII. Century Poetry in the Light of XVIII. Century Critical Theory."

THURSDAY, OCTOBER 26...Concrete Institute, 296, Vauxhall Bridge-road, S.W., 8 p.m. Mr. R. L. Humphreys, "Fireproofing."

Camera Club, 17, John-street, Adelphi, W.C., 8.30 p.m. Mr. A. Cheese, "A Winter Holiday in Greece."

FRIDAY, OCTOBER 27...Physical, Imperial College of Science, South Kensington, S.W., 5 p.m. 1. Hon. R. J. Strutt, "Further Observations on the Afterglow of Electric Discharge and Kindred Phenomena." 2. Professor C. G. Barkla and Mr. J. Nicol, "Homogeneous Fluorescent X-radiation of a Second Series."

SATURDAY, OCTOBER 28...Educational Handwork Association, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 3 p.m. Lecture by Mr. B. P. Ballard.

Journal of the Royal Society of Arts.

No. 3,075. VOL. LIX.

FRIDAY, OCTOBER 27, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

ROCK CRYSTAL: ITS STRUCTURE AND USES.

By Alfred E. H. Tutton, M.A., D.Sc., F.R.S.

Lecture IV.—Delivered May 22nd, 1911.

The applications of quartz to both scientific and artistic purposes, as well as to industry, are so numerous and varied that a separate lecture may well be devoted to them, and can, indeed, by no means exhaust them.

The coloured varieties of transparent quartz crystals have since very early times been highly valued as gem-stones, and of these amethyst, which proved so interesting on investigation in the last lecture, is, perhaps, the most important. The violet colour, its great attraction, is due to a minute trace, so slight as to be almost chemically undetectable, of an oxide of manganese, which appears to be concentrated between the lamellæ. It was shown in the last lecture that the violet colour is usually only developed in alternate sectors of about 60°, which are revealed with great clearness when a section-plate is cut perpendicularly to the axis, for polariscopical investigation, and that the lamellar twinning is exhibited chiefly in the parts which are thus naturally coloured violet. A very fine example of such a section-plate, three inches in diameter, is exhibited on the lecture table, and a photograph of it on the screen. The violet sectors usually close up near the centre, so that the whole of the central part of the crystal is violet-coloured and composed of rapidly repeated twins. This part, moreover, exhibits no trace of optical activity in parallel polarised light, and affords the ordinary uniaxial interference figure in convergent polarised light, the black cross being complete right up to the centre; for the two varieties of quartz, right- and left-handed, are so intimately blended, that any effect due to the one is neutralised by an equal and opposite effect due to the other, affording a beautiful illustration of the property of pseudo-racemism, alluded to in the last lecture, on the large scale.

But it must not be taken for granted that this interesting lamellar twin structure in quartz is confined to violet crystals, and altogether to the violet sectors; for many crystals show it which are either perfectly colourless, or slightly yellow, or which only show a faint trace of the violet colour when held up to the light. If a trace of colour be present, however, the twin lamellæ are usually just perceptible even in ordinary light, when the section is regarded at some particularly suitable angle. Amethysts, and, in fact, all quartz crystals showing the laminated structure, break with the well-known "ripple" fracture. An interesting theory has been put forward by Professor Judd that the lamination is due to the movement of the molecules of the alternate layers along glide planes, and he has shown that quartz does possess such planes of possible gliding, parallel to the rhombohedral faces. Such gliding, when carried out above a certain limit, results in permanent inversion of the positions of the molecules, and this could well be effected by the simultaneous action of high pressure and temperature, subsequent to the formation of the original crystal. For there is considerable evidence that the purple tint was developed subsequently to the first crystallisation, and that it was due to a change in the state of oxidation of the manganese, probably as the result of the physical forces at work in effecting the gliding of the molecules of alternate laminæ.

When the colour of quartz is yellow, it is usually due to a trace of ferric oxide. The bright topaz-yellow crystals are usually known as "citrine," and those not so brightly yellow, and also those possessing a brown appearance, are included under the name of "cairngorm," a

name derived from the locality (Banffshire) in Scotland where some of the finest specimens have been found. It is very interesting to read in "Leaves from the Journal of Our Life in the Highlands," by her late Majesty Queen Victoria, that on several occasions the late Prince Consort, who took so keen an interest in everything pertaining to natural knowledge, and who was himself a very good mineralogist, discovered and brought to her Majesty beautiful specimens of cairngorm and of other varieties of rock crystal, or suggested to the party a search for such crystals, which eventually proved successful, during their delightful rambles among the glens and mountains around Balmoral. We find, for instance, in the account of the ascent of Ben-na-Bhourd, that near the top "We came upon a number of 'cairngorms,' which we all began picking up, and found some very pretty ones"; also that during the return journey "Albert found some beautiful little rock crystals in the Sluggan." Again, on the occasion of the ascent of Ben Muich Dhui, "We all began walking and looking for cairngorms, and found some small ones."

These reminiscences of the Prince Consort, who was one of the best friends of the Royal Society of Arts, will doubtless afford particular pleasure in this place. They once more emphasise the great loss that Science in this country suffered in the premature demise of one who was so rapidly developing the means of effectively spreading abroad amongst our people both the taste for and the means of cultivating the knowledge of science, and who realised so deeply its immense influence on industry and on the well-being of the country.

The darker varieties of brown or brownish-yellow crystals, and also all black crystals of quartz, are included under the name "smoky quartz," although the special name of "morion" has been given to the beautiful black crystals lining cavities in granite in the Mourne Mountains of Ireland. The beautiful pale rose-coloured quartz, so valued as ornaments, and which is associated with manganese minerals in masses of granite in Bavaria, like amethyst, is supposed to owe its colour to oxide of manganese, and the fact of this association with manganese minerals is strong presumptive evidence that the conclusion is correct.

The name amethyst was given to the purple variety of quartz crystals, according to Pliny, from the belief which was rife among the Greeks that the possession of the stone was a preventive against intoxication by the purple wine cup, being derived from ἀμέθυστος. Plutarch suggests, however, that the name is connected with the colour of amethyst; for if the purple wine be watered down to the colour of amethyst it is then too weak to intoxicate. It was greatly valued by the Greeks and Romans as a gem-stone, but the discovery of such large quantities in Brazil, Ceylon, and Siberia in recent times has reduced its market value, a result which has been also aided by the ease with which coloured glasses of similar tint can now be made. Indeed, so long ago as the year 1690 very good imitations were produced in France, which, in the absence of accurate knowledge of the optical properties of quartz, were almost impossible to be distinguished from true quartz amethysts.

It is deeply interesting to recall that rock crystal was so well known to the ancient Egyptians, and even to the Hittites, Assyrians, and Babylonians, that necklaces, seals, and engraving cylinders were quite in common use, and are now frequently discovered by Egyptologists and other archæologists. We are informed by Mr. C. W. King, in his fascinatingly interesting "History of Decorative and Ornamental Stones," that the earliest known work on such stones is that of Theophrastus, who wrote in the fourth century B.C., and that he refers to rock crystal as being greatly used for decorative purposes in his time. The Romans, however, were successful in discovering such large and perfect crystals, as their empire extended, that it was quite the fashion to use cups and vases of carved quartz for their iced drinks and floral displays, and fabulous sums are recorded as being given for the best of these lovely objects of art. For instance, Pliny tells us of a lady of the less opulent class who gave the Roman equivalent of £1,500 for a carved bowl of rock crystal. The story of Nero in one of his rages smashing two priceless bowls of quartz, engraved with designs from Homer, is also well authenticated. Perhaps one of the most curious stories from Roman life, however, is that told by Seneca, concerning Vedius Pollio, a wealthy Roman, who had been so fearfully enraged by one of his boy slaves having broken a crystal vase that he ordered the boy to be thrown into a lamprey pond, to be eaten alive. The boy escaped and sought the Emperor Augustus, to whom he petitioned for a less horrible death. Augustus was so struck with the cruelty of the sentence that he ordered the boy's release, and that all Pollio's collection of vases and cups of rock crystal should be broken

in pieces, and that the lamprey pond should be filled up.

As the luxury of the Romans increased, and larger and larger crystals were discovered, the vases and other objects of art carved from them became embellished with raised mouldings, and engraved with foliage and flowers, and with the figures of animals, deities and men and women. Lucius Verus is said to have possessed a crystal bowl so large that no man could be found to quaff the whole of the contents at one draught; and a still more remarkable story is told by Mohammed Ben Mansar of a merchant in Mauritania possessing a basin composed of only two pieces of rock crystal, and which was so large that four men could sit in it at once. Doubtless this is somewhat of an exaggeration, but Mr. King informs us that in the treasury of Ghisneh, when captured in A.D. 1159, four crystal vases were found, each of which would hold two skins of water.

It is a well-known fact that at many Roman feasts the crystal cups were retained by the guests, a perfectly vouched for instance being at the wedding of Caranus, when each guest was presented with the Murrhine or Alexandrine rock-crystal cup from which he drank the health of the bride and bridegroom. Also at the celebrated dinner given by Lucius Verus, which is estimated to have cost £60,000 of our money, the party being only twelve in number, after each course both the crystal cups and the plate, and also the slaves who waited upon the party, were presented to the fortunate guests.

In the later periods of Imperial Rome, quartz rings, carved from the solid crystal, were very much worn, and the Arabs became very expert in the art of working these rings out of rock crystal. When we remember that the hardness of quartz is 7° in the scale of hardness, that is, that quartz is as hard as or harder than steel, and that only topaz, corundum, and diamond are harder, we may wonder at and admire the more the extraordinary skill of these early carvers. The largest mass of quartz recorded as being ever seen by the Romans was the ball of quartz, 50 lbs. in weight, which was dedicated in the Capitol by Livia. A bowl which held two quarts is also referred to as having been in use at the same time. Spheres of crystal are not infrequently discovered amongst much earlier remains, for instance at Nineveh, where they were used as burning-glasses. In Roman times such spherical lenses were employed by surgeons for cauterising wounds, and Pliny says: "I find it asserted by surgeons that when any part of the body requires to be cauterised it cannot be better done than by means of a crystal ball held up to the sun's rays." Balls of crystal were also greatly valued for another remarkable property of quartz, which has not yet been referred to, namely, its extraordinary coldness to the touch. It was quite a customary thing for a wealthy person to hold a ball of quartz in the hand during the heat of midsummer, its refreshing coolness being most grateful. Mr. King gives two quotations from Propertius which express this fact quite clearly :—

"Oh what avails the purple's Tyrian glare,
Or that my hands the limpid crystal bear?"

"Now courts the breeze with plumes of peacocks fanned,
Now holds the flinty ball to cool her hand."

In the mystical writings attributed to Orpheus by the religious cult founded in his name are found several allusions to crystal spheres. A ball of rock crystal is recommended as the most proper means of kindling the sacrificial fire, the sphere being thus used as a burning-glass, a spherical lens in fact, and the fire thus produced was known and venerated as the "fire of Vesta."

There was a long interval during the dark ages following the break-up of the Roman Empire when we hear little of the uses of rock crystal. But with the Renaissance came a remarkable revival of artistic work in quartz. This material was employed for the most important intagli, caskets, medallions, and plaques. For instance, one of the principal works of Valerio il Vincentino was a coffer adorned with plaques of crystal portraying the history of the Passion, which he was commissioned by Clement VII. to prepare at the price of 2,000 gold scudi as a present for Francis I. Michael Angelo also prepared numerous designs for plaques of rock crystal. Moreover, the construction of crystal vases was resuscitated, and there is an actual inventory in existence of the works of art in rock crystal which had been accumulated by the French monarchs up to the fatal year 1792, which places their value at no less than £40,000. The Milanese in particular distinguished themselves by their skill in crystal cutting, and the names of Ciuliano Taverna and Annibal Fontana stand out prominently as masters in the art of making intagli and cameos; there is a record of the latter having constructed a crystal coffer for the Elector of Bavaria, for which he received 6,000 scudi.

By the very great kindness of my friend Mr. Alfred Simson, I am enabled to exhibit on the lecture table nine exquisite examples of

this ancient and revived art. The most antique, and possibly the most interesting, is a Buddhist reliquary from Ceylon, probably from Anuradhapura. Its probable date is about 300 B.C., or possibly a little later, and it is supposed to have once held a relic of the Buddha, Gautama. In general appearance it is not unlike a specific gravity bottle of larger size than usual, and it is ornamented with mouldings around the body and the stopper.

We have next a large bust of Augustus Cæsar, measuring 15 ins. by 10 ins., carved out of a single crystal, its period, unfortunately, not being known. Then we have a large crucifix, over a yard high, of rock crystal mounted in silver, the ends being engraved with religious figures. The cross stands on a skull, which surmounts a large block of crystal upon which are engraved emblems of the Passion. We have next four exquisite cups, two of them possessing carved covers. One of these cups is reproduced in Fig. 37; it takes the form of a conventional bird, driven in jewelled harness by a figure seated on the cover. It is of Austrian workmanship of the last century, and is mounted in silver-gilt and bejewelled with pearls, emeralds, and rubies, the crystal bird having a crown on its head besides being richly engraved. The second covered cup, represented in Fig. 38, takes the form of a nautilus. The cover bears the figure of a horse, and the prow-like front is surmounted by a child's head. It is also mounted in silver-gilt and adorned with numerous jewels, the crystal cup itself being deeply cut in relief with nautilus scrolls and mouldings. The other two are uncovered cups of German workmanship, enamelled and jewelled. One of them has a dragon for handle, enamelled in dark green and with the head projecting over the centre of the cup. The other, shown in Fig. 39, is of shell-form, and is mounted in silver-gilt and enamelled and jewelled. The diameters of these four cups vary from 7 ins. to 16 ins. There is also exhibited a plaque of quartz, nearly 7 ins. by 5 ins., engraved with figures of Christ and the Virgin, and possessing a richly carved and moulded rim, the plaque being of elongated octagonal shape. Also a tray is exhibited, 11 ins. by 9 ins. in size, of wonderfully clear quartz, of Indian workmanship, and engraved with a leaf design.

FIG. 37.—QUARTZ CUP IN THE FORM OF A BIRD, WITH COVER.

Besides these lovely objects of art on the table, we are enabled, by the kindness of the Keeper of the Rothschild Collection in the Waddesdon Room of the British Museum, to project on the screen lantern-slides of six exquisite specimens there exhibited. The most imposing is a two-handled covered cup 11 ins. high, of sixteenth-century German workmanship. It is mounted in gold, and enamelled and set with numerous jewels. The handles take the form of dolphins, and the

FIG. 38.—NAUTILUS-SHAPED COVERED CUP OF QUARTZ.

cover represents a stork with ruby eyes and with a gold collar round the neck. The bowl itself is of oval shape, and is engraved with representations of the triumph of Galatea. The foot in two stages is engraved with the figures of marine deities. The mounting is very rich, the general plan being an oblong fret in white enamel, each oblong enclosing an enamelled fruit, or a ruby or diamond, together with a gracefully looped cord, the loops being of ruby or emerald-coloured enamel.

The next in importance is a two-handled vase and cover of rock crystal, in the form of a compressed sphere, mounted in gold and also richly enamelled and jewelled. The sides are engraved with slender plants hanging from the top or springing upwards from the base. On one side is engraved a pear-shaped cartouche, with the name Akbar in Arabic characters. The scroll handles are carved with groups of fruit, and the base is cut in radiating gadroons, while the mount has four feet in scroll work and fruit, enamelled and set with four diamonds. This also is said to be sixteenth-century German work, although there are indications that it may be of Indian workmanship but reset in Germany.

We see next a lantern-slide of a ewer of rock crystal, the mouth and shoulder being in one piece, and the latter being engraved with vines and birds, while the lower part of the body, in another piece, exhibits figures of Neptune and sea-nymphs, beneath festoons. The upper and lower parts are held together by a broad gold band, with rubies and diamonds set in high relief alternating with groups of fruit in enamel. The mouth takes the form of a half-length lion with enamelled wings, and the stem and handle are also richly designed and carved and set with rubies and diamonds.

We next have a tall cup with cover, the body being bell-shaped and richly carved with deeply-cut diagonaled lines; the foot is ornamented with dragons and the cover surmounted by a wyvern. The whole is 10 ins. high, and came from the collection of Count Nostitz, of Prague.

The next slide represents a slender elongated bowl of rock crystal of Italian workmanship, also sixteenth century. The bowl is a narrow oval, curved inwards at four points where the engraving represents entwined dragons. The rest of the bowl is ornamented with acanthus leaves springing from the stem. The baluster stem is also of clear crystal filled in with black and translucent enamels. The foot bears an acanthus quatrefoil in relief. This object is altogether one of the most graceful and elegant examples of work in rock crystal.

The last of these slides represents a plaque of quartz oval in shape and engraved in intaglio,

FIG. 39.—SHELL-LIKE QUARTZ CUP, UNCOVERED.

the subject being a deeply interesting one; for it is a copy of the fresco of the Sale of Cupids discovered at Herculaneum in June, 1759. The rim is mounted with gold, which is enamelled with studs and bands. The size of the plaque is 6 ins. by 5 ins.

Besides works of art in the form of useful objects and ornamental plaques, of which we have now seen some of the best examples, another use for quartz in the later Middle Ages, and even in more modern times, has already been alluded to, namely, for the construction of spherical balls for mystic and occult purposes. Two fine examples of such spheres of rock crystal are exhibited on the table, by the kindness of Mr. Henson and of Mr. Gregory, to the latter of whom, and to Mr. Butler, the lecturer is also greatly indebted for the excellent crystals of quartz with which these lectures have been illustrated. The balls are respectively of 4 ins. and 3 ins. in diameter.

A very famous sphere of rock crystal was the "show stone" of the celebrated Dr. John Dee, who, in the middle of the sixteenth century, was a Fellow of the then newly-established Trinity College, Cambridge. Dr. Dee lived through the reigns of Henry VIII., Edward VI., Mary, Elizabeth, and James I., and his literary and scientific writings are a most extraordinary mixture of fact, imagination, and mediæval astrology, while his reputed doings were often of the kind bordering on charlatanism and conjuring. He was frequently consulted as to the coming fates of his clients, and the crystal sphere was his chief stock-in-trade on such occasions. He died at Mortlake in the year 1608, at the ripe age of eighty-one.

The *modus operandi* of "crystal-gazers" is very various, but a common method is to support the sphere on an annular stand, the ring being just small enough to prevent the ball from falling through it, thus enabling the gazer to see right through the ball to the table below, which is generally darkened. Another favourite method is to hold the sphere in both hands, so as to avoid reflections. The observer sits with his back to the light, and gazes intently into the sphere, trying to think of nothing in particular and to be oblivious of surrounding objects. Five to ten minutes, or possibly sometimes longer, suffice in the case of a good "medium." The lecturer is assured on the authority of one well versed in the subject that it makes a great difference whether the ball be of real quartz or of glass, and has gathered the impression that the double refraction of quartz has something to do with this difference. Some very remarkable stories have been told of things thus seen, apparently in the sphere, but doubtlessly subjectively in the mind's eye, whatever that expression may mean, and statements are often made that events have actually occurred exactly as seen in the crystal globe. The lecturer has had no personal experience of these remarkable occurrences, but would be the last person either to deny what he has no exact knowledge of, or to assert their absolute trustworthiness as natural phenomena. He will content himself by saying that it is quite certain that we do not yet realise or know, or least of all understand, many of the forces and phenomena at work around us in nature. As Hamlet so truly says: "There are more things in Heaven and earth, Horatio, than are dreamt of in your philosophy."

We next come to an interesting fact about quartz, which has already been alluded to in passing, namely, its coldness, which is an excellent and immediate test as to whether an object be of quartz or only of glass. This property it owes to its high thermal conductivity. Quartz is a better conductor, according to Tyndall, than bismuth, lead and several other metals, and very much better than gypsum and most other transparent minerals. Sand, however, which, as we have seen, is quartz in a state of fine division, is a bad conductor merely because of its discontinuity, for each grain separately is a good conductor through its own substance. De Senarmont showed long ago that the conductivity is greater along the axis of the quartz crystal than perpendicularly to the axis. If two plates be cut, one parallel and the other perpendicular to the axis, and if, further, a fine hole be bored through each and a hot wire be stuck through a coating of wax laid over, the plate will melt around the wire in an ellipse in the case of the former plate, the longest diameter of the ellipse being parallel to the axis, while the wax will melt in a circular patch in the case of the plate cut perpendicularly to the axis. Spectacle-makers are well known to discriminate between quartz and glass lenses by the cooler feel of the former on applying the two in turn to the tongue.

This brings us to one of the most important of the applications of quartz, namely, the construction of lenses. Quartz spectacle lenses are much more permanent, less breakable, than glass ones, and provided they are constructed so that the axis is perpendicular to the tangent planes to their surfaces of curvature there is no appreciable double refraction introduced. For

the amount of the double refraction of quartz has been shown to be fortunately very small. The name "pebbles" has come to be given to quartz spectacle lenses from the fact that the quartz crystals used for the purpose of making spectacles come chiefly from Brazil, where they have been rolled over one another in loose heaps, or in the beds of mountain streams, for years and possibly ages, and so have become rounded into pebbles. They come mostly from the states of Goyaz, Minas Geraes, Bahia, and Rio Grande do Sul.

But besides the commercial use in spectacle-making, the construction of quartz lenses has now a very high scientific value, inasmuch as quartz is remarkably transparent to the non-visual rays of shorter wave-length than those of violet light, the so-called "ultra-violet rays," and also to certain waves of longer wave-length than those of red light, the "infra-red" of the spectrum, although in this latter case there are more absorption gaps. Practically all glasses absorb most of both the ultra-violet and infra-red rays, so that a train of quartz lenses and a quartz prism or prisms is an absolute essential for the spectroscopic study of these rays lying outside the visible spectrum. There is on the table a very fine spectroscope with complete quartz train of lenses and prisms, designed for this purpose, and constructed by Messrs. Hilger. The large 60°-quartz prism is of the kind recommended by Cornu, being composed of two 30° prisms, not cemented together by balsam but adhering firmly in contact owing to the true planeness of the surfaces; one is cut from a right-handed crystal and the other from a left-handed one, the optic axis being perpendicular to the junction-plane in both cases. By this device all optical activity (rotation) is neutralised and eliminated.

Still another scientific use for quartz has been found in the construction of standard weights. By the kindness of the Deputy Warden of the Standards, Major P. A. MacMahon, F.R.S., I am enabled to exhibit a set of standard weights belonging to the Standards Department of the Board of Trade, constructed from perfect crystals of quartz, no single flaw being anywhere discoverable. The largest is the standard kilogram. It was constructed, along with the smaller weights of the set, for the Standards Department by Dr. von Steinheil at Munich, in accordance with the recommendations of the Standards Commission. The crystal of which the kilogram was made was a Brazilian pebble of large size and nearly globular, which was procured by Mr. James Simms. The axis of the cylinder of each of the weights is parallel to the optic axis of the crystal from which it was cut. The density of the specimen, as determined by Dr. von Steinheil, was 2·65096. The great advantage claimed for this standard kilogram of quartz was that its weight remained constant, whereas metallic weights varied from time to time to a slight degree. Indeed, Dr. von Steinheil went so far as to say that "quartz alone maintains its weight invariable under all circumstances." Reversion has, however, recently been made to platinum-iridium as a more suitable substance for standard weights.

Another important scientific use was in the construction of an interference tripod of quartz, by Reimerdes at Jena, to replace the platinum one used by Fizeau in the well-known interference method of determining thermal expansions which was devised by Fizeau. It may be remembered that an improved Fizeau apparatus, which introduced the micrometric measurement

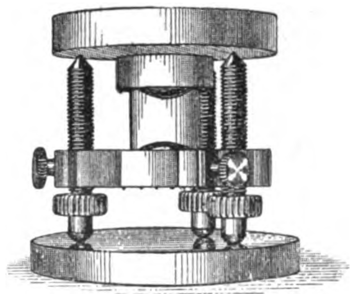

FIG. 40.—INTERFERENCE TRIPOD OF PLATINUM-IRIDIUM.

of rectilinear interference bands, instead of the use of curved fringes and signal points of reference which they were made to pass, was devised by Abbe and perfected by Pulfrich; and also that a still more convenient form was subsequently described by the lecturer. The tripod employed in the latter apparatus was constructed of platinum-iridium, and is represented in Fig. 40. The figure actually shows the arrangement used in determining the thermal expansion of a piece of porcelain tube, the latter being laid on the table of the tripod and covered with a disc of aluminium; the upper surface of the latter and the under surface of the large glass plate laid over the screws are the two surfaces which are caused to reflect the interfering light. The quartz arrangement as employed by Reimerdes at Jena with the Pulfrich dilatometer is shown in Fig. 41, *R* being the essential part, namely, a ring of quartz,

very much like that of porcelain shown in Fig. 40, cut from a plate a centimetre thick perpendicular to the axis of the crystal, and hollowed out somewhat so as to leave three places only on each surface, above and below one another, of the original thickness, in order to obtain the desirable three-point contact only with a ground-plate *G* and a cover-plate *D*, also both of quartz. The under surface of the upper plate bears a little silvered circular spot or ring, *m*, as a reference mark for observing the passage of the interference bands. The possibility of any reflection from the upper surface of the lower plate is avoided by matt-grinding, and the reflection from the upper surface of the cover-plate is eliminated sideways by making the two surfaces

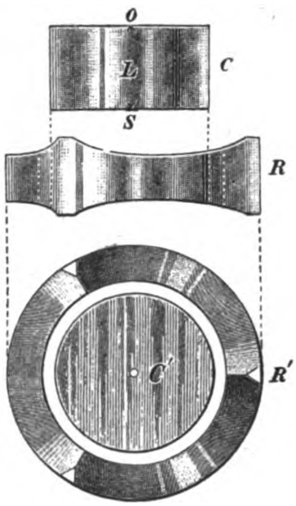
The value obtained by Reimerdes for the direction of the axis, as directly afforded by his quartz tripod, was :—

$$a = 10^{-8}(692 \cdot 5 + 1 \cdot 689t).$$

The coefficient of linear expansion along the axis is thus only half as much as that at right angles to the axis. The value for the axial direction is slightly less than that of platinum-iridium, which is 10^{-9} $(8600 + 4 \cdot 52t)$.

The advantages claimed for quartz as the best substance for an interference tripod are, that it is quite free from thermal lag or secular change, very regular in its change of expansion with the temperature, that the value is independent of the locality from which the quartz crystal is derived, and that quartz possesses greater hardness and more perfect elasticity than metals.

We now come to the last of the properties of quartz which can be touched upon in these lectures, but one which has extended its industrial use to an extent which is only just



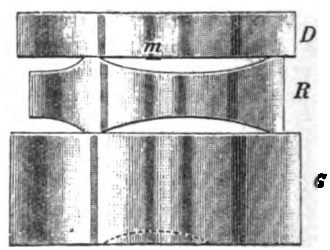


Fig. 41.—Tripod of Quartz Interference.

of the plate to be inclined at the small angle of 20 minutes out of strict parallelism, thus leaving the reflection from the under surface of the cover-plate alone visible. The second reflecting surface concerned in the interference is that of the object under investigation itself, which is of slightly less than 10 millimetres thickness and small enough in lateral dimensions to be placed within the quartz ring.

The coefficient a of the linear thermal expansion of quartz, as determined by Benoit with the Fizeau apparatus at Sèvres, for the respective directions of the axis and of the perpendicular thereto, are as under :—

For the direction of the axis

$$a = 10^{-8}(711 \cdot 1 + 1 \cdot 712t).$$

For that perpendicular to the axis

$$a = 10^{-8}(1316 \cdot 3 + 2 \cdot 526t).$$

beginning to be realised, namely, the fact that at the temperature of the oxy-hydrogen blow-pipe flame it fuses, and on resolidification forms a clear colourless glass of remarkable properties. The chief of these are that the transparent material thus obtained is almost unbreakable, that it will withstand sudden changes of temperature such as would at once shatter any glass, and that it possesses an elasticity which is well-nigh perfect, besides being an almost perfect electrical insulator, only wetting in contact with water with the greatest difficulty, and thus not attracting moisture at all. Quartz was first fused, as far as we are aware, by Gaudin in the year 1839, but it was Professor C. V. Boys who first acquainted us with the properties of fused quartz, in the celebrated research on the Cavendish experiment, for which he required a perfectly elastic suspension fibre, and found it in fused

quartz. It will be well remembered what interest was created by his exhibition of the production of such quartz fibres, by fusing a quartz crystal, attaching the viscous material to an arrow, and shooting the latter from a bow and thereby producing a quartz fibre as long as the room, both in this lecture theatre and at one of the conversazioni of the Royal Society some years ago. The fact that such a fibre of fused quartz is perfectly elastic rendered it an ideal filament for the suspension of his small golden spheres (attracted by larger leaden ones) in the Cavendish experiment, which enabled him to obtain the most accurate value yet arrived at for the density of the earth, namely, 5·5268.

For it was shown that two small spheres having a mass of one gramme each, when placed so that their centres were one centimetre apart, attract each other with a force of $6 \cdot 66 \times 10^{-8}$ dynes (the centimetre-gramme-second unit of force being termed a dyne), and this corresponded to the density of the earth just given. Quartz fibres also proved of inestimable service in Professor Boys' well-known radio-micrometer.

Fused silica glass is now a commercial material, being supplied on a considerable scale by the Silica Syndicate of 82, Hatton Garden, London, in a beautifully transparent form, and by the Thermal Syndicate of Wallsend-on-Tyne in an opalescent form, produced by means of the electric furnace, which is cheaper while being still fairly pure, the opalescence being due to the presence of air bubbles, from which the material of the Silica Syndicate is remarkably free. Silica glass is also made by two firms in Germany. By the kindness of Messrs. Johnson and Matthey, and of Messrs. Griffin, a large and typical collection of articles constructed of these two varieties of silica ware is exhibited on the lecture table. For such skill has now been acquired in the working of large quantities of quartz fused by the oxyhydrogen flame or in the electric furnace, the new implement of high temperature research and industrial progress now available, that most of the usual laboratory articles required by the chemist and physicist can be made in this highly refractory material. Quartz begins to soften at a temperature of 1500° to 1600° C., in the neighbourhood of the melting-point of platinum, and can be worked by skilled men at temperatures somewhat higher. Such apparatus of fused silica is almost indestructible, for it withstands sudden heating or cooling (such as heating to redness and then suddenly plunging into cold water) in a remarkable manner, and is well-nigh unbreakable, except by the use of quite unusual force, an ordinary fall on the floor rarely injuring it.

It is interesting that when quartz (specific gravity 2·651) is fused, the solidified cooled glass has only the specific gravity 2·21, there being thus a considerable reduction of density. Crystallographically this is important, as it shows that the molecules of silica are much more closely packed in the crystal than in the silica glass. Also the index of refraction is correspondingly lowered by fusion of quartz, that of the glass being 1·4585 (Gifford and Shenstone), whereas the two refractive indices of the crystal are $\epsilon = 1 \cdot 5534$ and $\omega = 1 \cdot 5443$. The reduction on fusion is in accordance with Gladstone's law, the specific refraction, which takes into account the density, remaining constant. Also the coefficient of expansion is remarkably reduced, for whereas that of quartz for the direction of the axis, the minimum expansion, has been shown to be 0·00000711, that of fused silica has been independently shown by Callendar and Minchin to be less than a tenth of this, the results of the two researches being 0·00000059 and 0·00000045 respectively.

For delicate operations in the laboratory silica glass is proving an inestimable boon, being far less readily attacked by acids (other than hydrofluoric) and other reagents than ordinary glass or porcelain. It is particularly suitable for the construction of weights, thermometers, vapour density apparatus, pyrometers, and all kinds of thermometers for ordinary purposes.

Moreover, it is now coming into use in metrology, and by the kindness of the Director of the National Physical Laboratory it is possible to exhibit a lantern-slide picture on the screen of a standard metre bar which has lately been constructed for the laboratory by the Silica Syndicate. Owing to its very small coefficient of expansion, and its constancy and durability, fused silica would appear to be particularly suitable for the material of a standard of length, provided experience should show that it is not subject to irregular secular change. There is practically no hysteresis within any possible range of temperature to which a standard of length would be subjected, direct experiments having established this fact satisfactorily. The standard takes the form of a transparent silica tube about two centimetres in diameter and a metre long, which merges at each end into a clear transparent horizontal slab of silica for the engraving of the reference lines. A silica knife-edged trunnion is fused into the bar at one

of the usual "Airy points" of support (those for which least flexure occurs), somewhat removed from the ends, the other point being indicated by a ring etched round the tube. The tube is thus a closed one, but it is pierced by two holes to permit of its submersion in water for temperature equalisation purposes. The reference lines are cut in a hard, closely adhering film of platinum, deposited on the silica, and protected by a cover slip. The reference lines are viewed and their positions read from the other side of the slab, the platinised side being arranged below. When the whole bar is immersed in water the optical images of the reference lines lie in the neutral plane of the bar, that of no flexure. The lines lend themselves to considerable precision, and are perhaps the finest ordinary lines that have yet been ruled.

The lecturer, however, has lately been experimenting with much finer lines, indeed lines of an altogether different order, ruled on quartz by Mr. H. J. Grayson, of Melbourne, of the fineness of 40,000 to the inch, the one forty-thousandth of an inch being the approximate wave-length of red light. Five such lines form the location-signal, the central line of the five being the reference line itself, proposed by the lecturer as the ultimate type of reference mark for standard metrology in wave-lengths of light, for which purpose even the finest of ordinary engraved lines are far too coarse, including many wave-lengths in their thickness. These lines on quartz are not so satisfactory, however, as the perfect ones ruled by Mr. Grayson on speculum metal, as quartz appears to splinter slightly along the edges of the lines. It would be very interesting to see what would be the effect of ruling such fine lines, one wave-length distance apart for red light, on polished slabs of fused silica, which might be expected to be less subject to splintering than crystallised silica is, possibly on account of its slight tendency to cleavage. It is to be hoped that this may shortly be put to the test of experiment. In any case fused silica is bound to prove of great value in the future of metrology.

In now bringing these lectures on rock crystal to a close, it may fairly be said that they have made it plain how exceedingly important and useful a material this mineral is, and that a whole course of lectures can by no means exhaust so fertile a subject. No mention has been made of the amorphous and semi-crystalline forms of natural silica, such as chalcedony and agate, or of the hydrated form of silica, opal, the varieties and combinations of which, and their impure but exceedingly beautiful forms, such as carnelian, onyx, jasper, sard, sardonyx, and chyrsoprase, so powerfully impress the mind with their exquisite colour, markings, and infinite variations. The prime object has been to indicate how perfectly quartz exemplifies the characters of a crystallised substance, and how instructive an example it affords of every property usually associated with a perfect crystal. Its uses in the arts and in industry have also been prominently brought forward in this last lecture of the series, and to the instruction derived with respect to the pure crystallography, optics, and other physical properties of quartz and of crystal structure in general, has thus been added abundant evidence of the rapidly-growing importance of this truly extraordinary mineral, in not only every variety of scientific work, but in regard to artistic adornment and the common purposes of everyday life.

THE MANUFACTURE OF PONT-L'EVÊQUE CHEESE.

Pont-l'Evêque cheese, one of the most favoured varieties known in France, is made in small squares four and a half inches wide and one inch thick. Its rich yellow colour is obtained by using a colouring matter, made from the pulp surrounding the seeds of the tropical plant *Bixa orellana*. It is one of the oldest brands of cheese known in France, having been made as long ago as the thirteenth century. It is estimated that £78,000 worth of Pont-l'Evêque cheese is manufactured annually, the principal centre of production being the district of Pont-l'Evêque in north-western France. The making of the cheese continues throughout the whole year, but the best results are always obtained in September and October. In the process of ripening, the mould, so important in the preparation of Brie and Camembert cheese, is not considered essential. Dependence is not placed on the germs in the air or surrounding substances, but upon the ferments, which are added to the milk by the rennet at the time of curdling. The curdling of the milk, an operation which forms the basis of all cheese-making, is obtained in the manufacture of Pont-l'Evêque by means of a commercial rennet. It is effected at a temperature of 89° to 94° F., depending on the outside temperature. The American Consul-General in Paris says that after the milk has been thoroughly strained, it is heated to the proper temperature for renneting. The rennet is then added, diluted in a quantity of water. Many cheese-makers add one-twentieth part of boiling water, so that the milk, which has an initial temperature of 89° or 90° F., is brought to nearly 94°. This is also the proper time for adding to the milk the required

amount of colouring matter. The coagulation completed, the breaking of the curd is begun. This is effected by cutting vertical slices in two opposite directions, forming angles of 45°. The division of the curd aids the separation of the whey from the curd. With a skimming ladle the curd is raised in thin horizontal slices, and placed upon mats of reed or rye straw. To prevent too rapid cooling, hot cloths are thrown over the curd. In about thirty minutes the separation of the curd from the whey should take place. Wooden boxes in the form of squares are used for moulding the cheese. These boxes are made of beech or ash, and the sides are pierced with holes. The curd is placed into the mould, little by little, with the fingers, care being taken to press it down firmly so that the lumps of curd will be free from surface fissures. After the mould is filled, it is turned over on a dry mat, this operation being repeated six or eight times within an hour. After about twenty-four hours the cheese is taken out of the moulds and the entire surface covered with a thin layer of fine salt, particularly the surface exposed to the air. Twelve hours later it is again turned and salted, special care being taken with the side exposed to the air. The next day marks the end of the salting process. Following the salting comes the drying, which takes place in the drying-room. In this room are placed open tables to receive the cheese, which is placed upon a layer of straw. The cheeses are turned over every day, and occasionally washed with additional colouring matter and light brine for a period of eight to twenty days according to the season. From the drying-room the cheeses are taken to the cellar. There they are placed on a plain surface, one against the other and covered with a cloth to prevent too great an evaporation. They are turned from time to time to ensure perfect uniformity in the ripening process, which is usually completed in about twenty days. The first quality cheese thus obtained is noted for delicacy of flavour and savouriness. Cheeses of the second class are always made during the spring and summer months, the milk used being that of the morning's milking added to that of the evening before. Before the curdling, there is added a quantity of boiling water equal to about one-fifth or one-eighth that of the milk. The third-class cheese is produced chiefly during the winter months. The milk of one, or even two days before is used, after having been skimmed. It is brought to the curdling point by the addition of boiling water. The principal markets for Pont-l'Evêque cheese are Pont-l'Evêque, Breuil-en-Auge, Beaumont, and Trouville, situated in the north-western part of France.

ARTS AND CRAFTS.

The London Schools.—The London Schools have now been at work for some weeks, and are apparently pursuing the even tenor of their ways, in spite of a certain amount of anxiety on the part of the teachers as to how the forthcoming changes in the examination arrangements may affect them later on. Most of the schools, probably, receive a larger grant from the London County Council than from the Board of Education, so that the trouble is not wholly financial, but there seems to be an idea that if the Board drops the elementary examinations it may have a bad effect on the numbers. That may be quite true, of course, but on the other hand, it is at least an open question whether the function of schools of art is to teach quite elementary students, and whether it would not be better to insist on some sort of elementary knowledge from students who wish to be admitted to them. Possibly, at the present moment most school of art teachers would answer that question by a rather emphatic "No"; not so much because they have any overwhelming desire to teach beginners as because they mistrust the quality of the training which students would be likely to receive before they came to them. That brings us to the much debated subject of the training of art teachers for ordinary secondary and primary schools, a subject which is well to the fore just now, thanks partly to the recent report on the Royal College of Art and the suggestions of the Council of the National Society of Art Masters. Something certainly urgently needs doing in this direction. The training department in connection with the Clapham High School is attempting something, it is true, and at least one of the training colleges for elementary school teachers is encouraging a few of its students to specialise in art. But this is not enough: there is undoubtedly a need for a system of training more definite and more far reaching, and carrying with it some kind of official recognition. Further, at this time of day any scheme which confined itself entirely to drawing, and did not make some provisions for training which would enable these teachers to give instruction, really efficient instruction as far as it went, in at least one simple craft, would be quite inadequate.

Many of the schools held, as usual, little exhibitions before the beginning of the session's work. These consisted sometimes of the work of actual students, sometimes of that of both present and past pupils. The disappointing thing about these little shows, from the point of view of the intelligent visitor, is that the best work has generally been on view before, either at the National Competition or at the London County Council exhibition. But, of course, the object of little collections of students' work of this kind is not so much to appeal to the outsider as to attract new pupils, and they certainly do enable intending students to see the kind of work that is being done at a school before they pledge themselves to attend it, though, perhaps, in some cases the work which really attracts is that of people who are by this time themselves teachers.

Furniture.—Though the spring is the best time for estimating what is going on as far as decoration proper is concerned, and for gauging the direction

in which pattern design is moving, there is generally a little spurt of activity in the early autumn. It is true that manufacturers of wallpapers and the like do not issue new patterns; those are reserved for the spring when, at the time of the yearly spring cleaning, householders are traditionally expected to renovate their domains. Still, amongst the numerous accessories which help towards decoration, there are always a goodly number of fresh things to be seen at this season of the year, when folk have returned from the country and are anxious to settle in comfortably for the winter before the cold weather is upon them. Amongst other things, there is a good opportunity of seeing how matters have been moving of late in the way of furniture design. To begin with, the idea, revived originally by some of the artist craftsmen, of making use of the grain of the wood to provide decoration for their furniture, has now evidently become thoroughly popularised, and is pretty often carried to excess. Some of the Australian woods, for instance, have very strong markings which, beautiful as their effect often is in small surfaces, want very careful handling on large pieces of furniture. When wood of this kind is used, say for large cupboards or bureaus, the effect is much more satisfactory when the panelling up is so schemed that, instead of continual patterned surfaces, we get plain unobtrusively marked wood, or at least broken effects, framing up the more definitely patterned portions. The eye wants some rest and, if it does not get it, speedily tires.

The simple, somewhat heavy furniture (mainly in oak) which came into vogue some years ago more or less as an accompaniment to the cry for the simple life, seems to have come to stay. It is now to be found practically everywhere as one of the types regularly supplied by commerce. Occasionally it has suffered from its popularity. We find it, for instance, most incongruously decorated with cheap and altogether unpleasant carving—evidently to suit the taste of customers who, whilst they have no love for simplicity, do not wish to be behind the times and are glad to clutch at the chance of what seems to them like a satisfactory compromise. Sometimes, on the other hand, the bedroom suites of this type err rather on the side of excessive rusticity, and we find washstands with tiled tops on which, apparently with the idea of producing a rough and countrified effect, the tiles instead, of being set as close together as possible, have a good ½ inch of jointing between them. As this is, of necessity, white, it looks very ugly with dark tiles, and is, of course, in any case extremely unpractical. But, whatever may be said against individual examples of this kind of simple furniture, it must be admitted that both it and some of the more elegant bedroom furniture are a very great improvement on the more pretentious and fussy suites which were the normal thing a few years ago—and which were quite hopelessly out of place in smallish suburban and country houses.

The rather pretty little simple marquetry patterns which were so pleasing a feature of some of the best made furniture a little while ago, seem to have fallen somewhat into disrepute. They are still being used, of course, perhaps rather more than they were, but not always with that discretion which helped to give them the success which originally they have undoubtedly had.

When we come to accessories, it is just worth noting how the introduction of glass jugs and hand basins has progressed. This is, perhaps, a natural reaction from the very dark, heavily glazed crockery constantly to be met with some time back. However that may be, glass ewers, etc., are very much to the front—some plain, more moulded, and a good many cut—whilst quite a number of them are enriched with gilding which looks very pretty when they are filled with water. In contrast, again, to some of the pottery shapes recently in vogue, these glass jugs are quite often very good in form.

Again, it is rather amusing to note how the prevailing fashion in ladies' dress has had its effect on the colour and design of cushion covers, which are now often to be seen in shades and patterns recalling not only the colour but the design of the fashionable guipures. Some of these patterns, by the way, are of a simple geometric type, which very few people would have looked at only a very short time ago.

EMPIRE NOTES.

The Destiny of Tonga.—It is rumoured that there is a movement afoot in the Colonial Office which may result in the Friendly Islands passing from the status of an independent kingdom, under British protection, to the position of an appanage of the Empire under the direct control of New Zealand. Should this prove to be well founded the rule of the South Sea chieftains will come to an end. No one who has followed diplomatic developments in the Western Pacific for the last decade can have any doubts as to the ultimate destiny of Tonga, but with the elimination of the protectorate the curtain will be rung down on one of the quaintest experiments in the art of government the world has seen. It seems a melancholy fate for a country, that aforetime rejoiced in the picturesque mimicry of European monarchism, to become a mere prosaic governmental department in the sphere of operations controlled by New Zealand. George Tubou I., a man of high character and ability, died actual king of the land. History links him up with the days of club law and spoils to the victor. The pomp and ceremonial of a court, feebly fashioned upon European models, was a poor business compared with the impressive strength of the king sitting in a "kara" ring, or conducting the affairs of state with the well-known club for sceptre. His grandson, Tubou II., the reigning chief, is a man of considerable power, though his kingship is of a different stamp from

that of his grandfather. It remains to be seen by what method of persuasion this independent race has been induced to become a part of the British Empire. When the Samoan group was divided between Germany and America, the Friendly Islands were recognised as being in the British sphere of influence, notwithstanding that there was a king, a parliament, a constitution, and all the paraphernalia of state. The real ruler of Tonga has been for many years past the High Commissioner, the Governor of Fiji. The process by which this petty kingdom becomes part of the Empire is analogous to the steps by which British rule has expanded in other parts of the globe.

The Maori Population of New Zealand.—It is interesting to observe that, while the Australian aboriginal is fast dying out, the Maori race in New Zealand is growing in strength and numbers. According to statistics taken from the census of last March, the total native population is computed at 49,350 — an increase in five years of 1,617—to which should be added 215 Maoris who live in the Chatham Islands. It is a difficult matter to procure accurate figures as to the number of half-castes. Probably most of these, as well as a large proportion of the Maoris themselves, are now living in European fashion. There has been a great difference in the observance of sanitary laws, and the natives are beginning to realise that the excessive mortality among their children has been caused to a large extent by insanitary conditions prevalent in their settlements. Generally speaking, the health of the natives has been exceptionally good, and in this respect they compare most favourably with other native races in countries occupied by Europeans. The public service is open to Maori youths, but the openings, for the most part, are limited. The Government, however, has always displayed a sympathetic regard for deserving Maori workers and those of fair education.

The Whaling Industry in South Africa.—The whaling industry is rapidly assuming large proportions in Natal and Cape Colony. At the present moment there are six or seven steam vessels employed in the trade at Durban, and it is no uncommon experience for these vessels to put to sea three times during a day, bringing back a whale each time. The profits of the industry are naturally large, and the regularity of captures of these monsters has given rise to a fear that before long the whale will be scared away from these shores, as was the case in New Zealand some years ago. There is no sign, however, of the supply of whales materially lessening. A large number of applications for shore sites have been addressed to the Government by syndicates, who desire to establish themselves at convenient positions along the south coast. It is stated that a company is being formed in Germany for the purpose of extending the industry to German East Africa. It is proposed to boil down the catch at a spot adjacent to Luderitzbucht. A company formed in British South Africa also has leased a portion of the foreshore in Sheerwater Bay, between Luderitzbucht and Dias Point. Here they are setting up a plant for the treatment of the whales harpooned in these seas.

Burma's Oil Industry.—In a recent report published on the administration of Burma, it is pointed out that there was a decrease in production in the smaller oil-fields of that country, due to exhaustion in 1909–10. Yenangyaung, it is true, had an enormous increase in production, but this was due rather to greater activity of working than to increased productiveness. New prospecting licences in the Magwe, Minbu, and Pakokku districts have been freely taken; the areas of all concessions held have been carefully scrutinised for new wells and new fields; and all companies are rapidly and largely increasing their storage capacity for crude oil on the fields. The completion of the Burma Oil Company's pipe line leaves the tank steamers of the Irrawaddy Flotilla Company, and of the River Transport Company, available for the transport of the products of other oil companies to the refineries in Rangoon. Several new refineries have been constructed in Syriam. The small Burmese refineries at Prome have been closed, with one exception, owing to the difficulties in obtaining crude oil.

Fruit-growing Experiments in British Columbia.—The Province of British Columbia has, for a long time, been exporting the finest fruits of the Dominion of Canada. This has been in a large measure due to the scientific and careful methods employed by the growers. Steps are now being taken by provincial horticulturists to extend their experimental operations, and to this end efforts are being made to establish one or more experimental fruit-growing stations in the Columbia-Kootenay Valley, one of which will be allotted to the Windermere district. Growers have been invited to offer small tracts to be used for the purpose. This magnificent valley, into which the Canadian Pacific Railway is building from both ends, contains the upper courses of both the Columbia and Kootenay Rivers, and has been settled for a number of years. It has long been thought that it should be possible to grow hardier fruits there than heretofore. The present demonstrated fruit area of Eastern British Columbia does not extend beyond the West Kootenay where, however, 150 varieties of apples alone are said to be grown. The various districts of the West Kootenay are already in possession of provincial demonstration orchards, the most notable being close to Nelson, which are operated as model orchards. It is estimated that the West Kootenay has 1,000,000 acres of fruit land not requiring irrigation, while the higher, dryer, and colder East Kootenay, including the Valley mentioned, has at least an equal area of land that is proved to be superior for general farming.

Electric Power in Ontario.—A representative gathering of prominent chemists and metallurgists attended the convention of the American Electro-Chemical Society held recently in Toronto. Toronto should, in time, become one of the greatest world centres for electro-chemical industries, and many of the American chemists express the opinion that Ontario has water-power facilities sufficient to render her the dominant manufacturing province of Canada. Dr. Buckland, of New York, and other authorities, have predicted considerable development in the mines of New Ontario by the aid of electrical power. On account of the absence of coal, and the difficulties of transport, there is nothing to prevent the demand for electrical power and its application to the reduction of ore on the mine itself, to which it may be easily and cheaply conveyed. Dr. J. W. Brown, of Cleveland, states that the electrical furnace was a practical proposition in these regions, where wood was plentiful and the necessary amount of carbon in the form of charcoal readily obtainable. Dr. Herring, of Philadelphia, stated that once cheap power could be obtained, the manufacturers would not hesitate to instal electricity even for baser metals. The drawback at present, he thought, was that distributors of current were too prone to charge the highest figure which the particular industry could bear, without any consideration as to the actual cost. Doubtless this method is a mistake, as the rapidity of electrical development depends very largely on cheapness. At the convention the practical working of the Ontario Government's hydro-electric system came in for special commendation. This system, as pointed out formerly in these columns, is a combination of Government control and private ownership. The Commission is able to buy power in bulk from private companies, and to act as distributor to towns and cities scattered over wide areas, on terms advantageous to the whole community.

American and Canadian Waterways.—The International Joint Commission appointed to deal with disputed questions between the United States and Canada is now complete, and a meeting of the American and Canadian Commissioners is about to be held at Washington. The Commission will take up, at its first meeting, the important question of the development and use of the waterways between the two nations. It will not concern itself, for the present, with the location of boundaries, but with the adoption of the waterways for industrial purposes, with the granting of permits for use, and with the conservation of the interests of the people on both sides of the border. Among the subjects to be considered will be plans for developing power in the St. John River, the development of the Richelieu River, and the outlet of Lake Champlain; for the development of water power in the St. Lawrence between New York State and the Province of Ontario; for a sanitary canal around Niagara Falls on the American side; for power development in the Rainy River, between Minnesota and Canada and in the Lake of the Woods; and for the use of waters in Montana and Saskatchewan for irrigation purposes. All these objects are excellent, and the accomplishment of them will tend to the advantage of both countries. By the appointment of this Commission it will be possible for the negotiations between the United States and Canada to be conducted direct instead of being made dependent upon diplomatic communications between Washington and London.

Canadian Coinage.—The new Canadian "cents." appear without the time-honoured "Dei Gratia," or any equivalent therefor, on the face of the coins, so that, so far as this coinage issue is concerned, the name of God is omitted. Read in the light of the fact that, years ago, Anglo-Saxon countries pointed scornfully at France for omitting the name of the Deity from their coinage, and of the recent decision of the Congress of America to retain the phrase "In God we trust," which Mr. Roosevelt had proposed to omit, the action of the Canadian authorities is likely to be adversely commented upon both in America and in the United Kingdom. Why the dies sent out to the Canadian Mint differ in this respect from those used in this country seems to require explanation. Although, for the moment, the alteration in the Canadian coinage does not appear to have attracted much attention in the Dominion, there is little doubt but that the matter will excite some comment among Canadians, many of whom will not care to be regarded as less reverential or religious, even in their coinage, than the old country, or than their neighbour, the United States.

CORRESPONDENCE.

DEW-PONDS.

With reference to Colonel Pitt's letter in last week's *Journal*, and his observation that the dry summer has afforded an opportunity of testing the tradition that "dew-ponds" derive their supply of water from dew or mist, it may be pointed out that there has been very little dew and very little mist during the summer, so that the basis of the test is lacking. Heavy dews and mists occur chiefly on clear, calm nights, when the air is damp; but unusual dryness of the air has been a marked feature of the summer, and there has often been a creep of air or a breeze during a considerable part of the night. There have, of course, been dews, but it was notable how often one was able to walk on grass late in the evening or at night without getting one's boots damp; and even after clear nights there have been mornings when the grass has been hardly damp, very far short of the drenched condition of grass so usual on English mornings in August and September, and even in June and July. Deposition on the surface of water warmed by the day's sunshine, if it does occur in

normal summers, would lag far behind the deposition on grass.

The matter of gain and loss of moisture has interested me in connection with water supplies in dry countries with bright sunshine; and during this summer I was struck by the great effect which the long duration of sunshine in these latitudes may have, in spite of its flatter angle at noon, compared with southern Europe or the tropics.

Even if there had been heavy dews and mists during the summer, the correctness of the dew-pond theory would not have been tested. It is a matter of balance, whether the pond gains or loses, and the hot sunshine, unusually effective in the early morning, and late evenings, owing to the lack of mist, might easily have turned the scale to loss, especially as there has been an unusual amount of dry easterly and north-easterly breeze.

I do not here consider the question whether the dew-pond theory is true or untrue, this letter being confined to two points: first, that there has been little dew or mist this summer; and, secondly, that even if there had been heavy dews and thick mists, the forces of evaporation during this summer might have been strong enough steadily to reduce the stores of water in the ponds.

ORIENTAL CARPETS.

The note about the Oriental carpet trade in last week's *Journal* prompts me to add what will, perhaps, be fresh information to some readers of the *Journal*.

The export of Oriental carpets from Smyrna and Constantinople has been falling off for some years as regards British ports, probably in consequence of the increased export direct to Germany.

The reason for this is that until a few years ago Germany obtained her Oriental carpets in London, but has since found it increasingly easy to import them direct.

The fiscal arrangements of the countries in question are directly responsible for our loss of this trade, which was, not many years ago, entirely in our hands. The fiscal policy of Great Britain with regard to this trade has been precisely what would have been devised to make the trade impossible, and the natural result has followed.

It is too late for us to do anything to recover our trade to Germany in Oriental carpets, and the time is perhaps coming when we shall be buying from Germany, so successfully are our rivals handling the goods.

A much more important side of this question, however, is the effect it will have upon our home industry of carpet weaving. The Oriental carpets now coming to this country take the place of goods that might be made here, and I estimate that were this trade secured there would be employment for 20,000 carpet weavers in addition to those at present employed in this country.

The manufacturers of carpets in this country have at present to face the competition of all the world without any assistance or protection from national policy. No other country is so situated, and, on the the other hand, Turkey, Austria, and Germany have advantages in lower labour rates, which put their products in our markets at far less than our cost. An import duty would put up prices, but in the case of a carpet of which the price is already high, would that seriously matter? A man buys a real Turkey carpet only once or twice in his lifetime, and an enhanced price would be no hardship to the consumer in the case of these goods.

C. A. HINDLEY.

October 24th, 1911.

OBITUARY.

THE EARL OF ONSLOW, G.C.M.G.—The Earl of Onslow died at Hampstead on the 23rd inst. at the age of fifty-eight. Educated at Eton and Exeter College, Oxford, he soon developed a faculty for administrative work and an interest in public affairs. In 1887 he served as Under-Secretary for the Colonies; in the following year he was appointed Parliamentary Secretary to the Board of Trade, and from 1888 to 1892 he acted as Governor and Commander-in-Chief of New Zealand. During this period was born his second son, the Hon. Huia Onslow, who received a Maori name in honour of his birthplace, Maoriland. Three years after his return from New Zealand Lord Onslow was appointed Under-Secretary of State for India, and in 1900 he returned to the Colonial Office for a further period of three years. In 1903 he became President of the Board of Agriculture, and it was here, perhaps, that his best work was done. Himself an owner of over 13,000 acres, he was keenly interested in all kinds of agricultural questions, and during his term of office at the Board he appointed important departmental committees to inquire into sheep-dipping, the Fertilizers and Feeding Stuffs Act, the fruit industry, and railway rates, all questions of vital importance to agriculturists.

In 1905 Lord Onslow was appointed Chairman of Committees in the House of Lords, a post which he only resigned last spring on the ground of ill-health. He was also a member of the House of Lords Select Committee which, with Lord Rosebery as chairman, sat to consider the reform of the Second Chamber.

Lord Onslow became a member of the Royal Society of Arts in 1903. He had previously taken the chair here on two occasions: in 1893, at a meeting of the Colonial Section when Mr. (now Sir) Westby B. Perceval read a paper on "Aspects of Imperial Federation, from a Colonial Point of View," and in 1899, when Mr. H. A. Acworth, C.I.E., read a paper on "Leprosy in India" before the Indian Section.

COLONEL THOMAS MYLES SANDYS, D.L.—Colonel T. Myles Sandys died on the 18th inst. at his London residence in Jermyn Street. Born in 1837, he was educated at Shrewsbury. He entered the service of the East India Company, and served through the Indian Mutiny in the 73rd Bengal Native Infantry. He afterwards exchanged to the 7th Royal Fusiliers, in which regiment he served for twenty years. He was subsequently lieutenant-colonel of the 3rd Battalion (Militia) of the Loyal North Lancashire Regiment, retiring as honorary colonel in 1897.

Colonel Sandys represented the Bootle division in Parliament from its creation in 1885, until his retirement in March last. He was deeply interested in all matters connected with the Army and Navy. He became a member of the Royal Society of Arts in 1879.

NOTES ON BOOKS.

COLLECTIVE INDEX OF THE "JOURNAL OF THE INSTITUTE OF BREWING": 1887-1910. Compiled by William H. Bird, A.C.I.S. London: Harrison & Sons. 10*s*. 6*d*.

Since 1895 the *Journal of the Institute of Brewing* has formed a complete record of scientific and practical work carried out in connection with brewing, malting, distilling, and the allied industries, in all parts of the world. The collective index, which is an exhaustive book of reference to the Journal, covers 550 pages. Divided into four parts — (1) Authors, (2) Subjects, (3) General Matter, and (4) List of Journals from which papers have been abstracted—it has been made, by this means and by a system of cross-indexing, almost impossible to miss any reference having a bearing upon the subject to be traced. Part (4) probably represents the most complete list of journals of interest to the fermentation industries extant.

STEVENS' MERCANTILE LAW. Fifth Edition. By Herbert Jacobs, B.A. London: Butterworth & Co. 10*s*. 6*d*.

The fourth edition of this well-known manual appeared eight years ago, and since that date it has been twice reprinted; but in the meantime the law has undergone several important changes owing to statutory enactments and decisions of the courts. The present edition has been revised by Mr. Jacobs (who was also responsible for the third and fourth editions), and brought thoroughly up to date. Thus the chapter on Marine Insurance has been rewritten in the light of the codifying Act of 1906, while another improvement is that the dates of all cases cited are now given.

The book is divided into five parts: (1) General View of the Law of Contracts; (2) Rules Relating to Parties to Contracts; (3) Rules Relating to Subject-matter of Contracts; (4) Bankruptcy; and (5) Arbitrations. There is also a useful appendix on patents, trade-marks, and copyright, and a very full table of the statutes cited in the volume.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, OCTOBER 30...Cold Storage and Ice Association, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. Major A. E. M. Norton, "Some Suggestions for the Improved Marketing of Frozen Produce."

East India Association, Caxton Hall, Westminster, S.W., 4 p.m. Colonel Sir Thomas Hungerford Holdich, "The Gates of India."

Engineers, Junior Institution of, at the Institution of Electrical Engineers, Victoria-embankment, W.C., 8 p.m. Mr. George Evetts, "Notes on Design and Construction in Gas Works."

London Institution, Finsbury-circus, E.C., 5 p.m. Mr. Oscar Browning, "The Study of History."

Architectural Association, 18, Tufton-street. S.W., 7.30 p.m. Mr. H. H. Hill, "The A.A. Excursion to the Loire."

TUESDAY, OCTOBER 31...Sociological, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. Dr. Gilbert Slater, "The Universities and the Democracy."

Photographic, 35, Russell-square, W.C., 8 p.m. Mr. F. G. Newmarch, "A Glimpse of Spain."

WEDNESDAY, NOVEMBER 1...Public Analysts, at the Chemical Society's Rooms, Burlington House, W., 8 p.m. 1. Messrs. H. S. Shrewsbury and A. W. Knapp, "Notes on Shrewsbury and Knapp's Process for Estimating Cocoanut Oil." 2. Mr. H. S. Shrewsbury, "Note on a Counterfeit Gold Coin." 3. Mr. L. M. Nash, "Note on the Examination of Finnish Turpentine." 4. Mr. L. Reed, "Note on the Approximate Estimation of Starch by Iodine." 5. Mr. E. H. Miller, "Note on the Gravimetric Estimation of Phosphorus in Milk." 6. Dr. J. McCrae, "Kobert's Reagent as a Test for Salicylic Acid." 7. Mr. Wilson H. Low, "Precipitation of Nickel Compounds and Preparation of Spongy Nickel."

United Service Institution, Whitehall, S.W., 3 p.m. Colonel A. J. A. Wright, "The Probable Effects of Compulsory Training on Recruiting for the Regular Army."

Royal Archæological, at the Society of Antiquaries, Burlington House, W., 4.30 p.m. Mr. A. Hamilton Thompson, "The Registers of John Gynwell, Bishop of Lincoln, for the year 1349."

THURSDAY, NOVEMBER 2...Child Study, 90, Buckingham Palace-road, S.W., 7.30 p.m. Mr. H. Holman, "Psychology and Grammar."

Chemical, Burlington House, W., 8.30 p.m. 1. Messrs. F. B. Power and T. Callan, "The Constituents of the Seeds of Casimiroa Edulis." 2. Messrs. P. von Romburgh and G. Barger, "Preparation of the Betaine of Tryptophan and its Identity with the Alkaloid Hypaphorine." 3. Messrs. G. Barger and W. W. Starling, "β-2-methoxy-naphthylpropionic Acid and Methoxy-peri-naphthindanone." 4. Messrs W. J. Pope and J. Read, "Dihydroxydihydrindylamine and its Resolution into Optically Active Components." 5. Messrs. A. Senier and R. Clarke, "Studies in Phototropy and Thermotropy. Part II.—Naphthylideneamines." 6. Mr. A. J. Ewins, "Some Derivatives of 4-(or 5)-methylglyoxaline." 7. Mr. J. W. Dodgson, "The Stability of the Double Oxalates of Sodium and Nickel, and Sodium and Cobalt." 8. Messrs. M. J. Burgess and R. V. Wheeler, "The Lower Limit of Inflammation of Mixtures of the Paraffin Hydrocarbons with Air."

London Institution, Finsbury-circus, E.C., 6 p.m. Mr. A. B. Keith, "The Development of the Constitution of the Commonwealth of Australia."

Camera Club, 17, John-street, Adelphi, W.C., 8.30 p.m. Dr. Tempest Anderson, "Matavanu, a New Volcano in Savaii."

Rontgen, 20, Hanover-square, W., 8.15 p.m.

Journal of the Royal Society of Arts.

No. 3,076. VOL. LIX.

FRIDAY, NOVEMBER 3, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICE.

ARRANGEMENTS FOR THE SESSION.

The Opening Meeting of the One Hundred and Fifty-Eighth Session will be held on Wednesday evening, November 15th, when an address will be delivered by LORD SANDERSON, G.C.B., K.C.M.G., I.S.O., Vice-President and Chairman of the Council. The chair will be taken at Eight o'clock.

The following arrangements have been made for meetings before Christmas:—

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock:—

NOVEMBER 22. — JAMES DOUGLAS, LL.D., Past President Am.Inst. Mining Eng., "The Industrial Progress of the United States of America."

NOVEMBER 29. — A. E. BERRIMAN, "The Efficiency of the Aeroplane."

DECEMBER 6.—J. A. J. DE VILLIERS, "British Guiana and its Founder, Storm Van 's Gravesande." LORD REAY, G.C.S.I., G.C.I.E., LL.D., will preside.

DECEMBER 13.—W. YORATH LEWIS, M.Am. Soc.M.E., A.M.Inst.Mech.E., A.M.Inst.E.E., "Continuous Service in Passenger Transportation."

INDIAN SECTION.

Thursday afternoon, at 4.30 o'clock:—

DECEMBER 14.—J. TRAVERS JENKINS, Ph.D., D.Sc., Superintendent of the Lancashire and Western Sea Fisheries, "Fisheries of Bengal."

CANTOR LECTURES.

Monday evenings, at 8 o'clock:—

PROFESSOR VIVIAN B. LEWES, "The Carbonisation of Coal." Four Lectures.

Syllabus.

LECTURE I.—NOVEMBER 27.—*The Composition of Coal.*

LECTURE II. — DECEMBER 4. — *The Methods Employed in the Destructive Distillation of Coal.*

LECTURE III. — DECEMBER 11. — *The Thermal Conditions existing during the Carbonisation of Coal.*

LECTURE IV. — DECEMBER 18. — *The Possible Improvements in Carbonisation.*

Papers to be read after Christmas:—

CECIL THOMAS, "Gem Engraving."

F. MARTIN DUNCAN, "The Work of the Marine Biological Association."

H. A. ROBERTS, M.A., "The Relations of Science to Commerce and Industry."

JOHN NISBET, D.Oec., late Conservator of Forests, Burma, "The World's Decreasing Timber Supplies."

FRANK WARNER, "Silk."

CHARLES C. ALLOM, "The Development of Artistic Skill in the Applied Arts."

CYRIL DAVENPORT, "Illuminated MSS."

ERNEST KILBURN SCOTT, A.M.Inst.C.E., M.Inst.E.E., "The Manufacture of Nitrates from the Atmosphere."

CHARLES BRIGHT, M.Inst.E.E., "The Administration of the Imperial Telegraphs."

HAROLD COX, "The Interdependence of Morals and Economics."

PROFESSOR G. W. OSBORN HOWE, "Recent Progress in Radio-Telegraphy."

E. D. MOREL, "British Rule in Nigeria."

GORDON CRAIG, "Stage Illusion."

THEODORE E. SALVESEN, "The Whaling Industry of To-day."

LEONARD HILL, M.B., F.R.S., and MARTIN FLACK, M.A., M.B., B.Ch., "The Influence of Ozone in Ventilation."

E. A. GAIT, I.C.S., C.I.E., Census Commissioner for India, "The Indian Census of 1911."

WALTER SAISE, D.Sc., M.Inst.C.E., F.G.S., "The Coal Industry and Collier Population of Bengal."

W. A. LEGG, M.Inst.C.E., "Irrigation in South Africa."

ALAN BURGOYNE, M.P., "Colonial Vine Culture."

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock:—

January 18, February 8, March 14, April 25, May 16.

COLONIAL SECTION.

Tuesday afternoons, at 4.30 o'clock:—

January 30, February 27, March 26, May 7.

CANTOR LECTURES.

Monday evenings, at 8 o'clock:—

VAUGHAN CORNISH, D.Sc., F.G.S., F.C.S., "Ocean-Waves, Sea-Beaches, and Sandbanks." Two Lectures.

January 22, 29.

LOUDON M. DOUGLAS, "The Meat Industry." Three Lectures.

February 5, 12, 19.

LUTHER HOOPER, "Hand-Loom Weaving." Three Lectures.

February 26, March 4, 11.

NOEL HEATON, F.C.S., "Materials and Methods of Decorative Painting." Three Lectures.

March 18, 25, April 1.

HOWARD LECTURES.

Monday evenings, at 8 o'clock:—

CAPTAIN H. R. SANKEY, R.E., M.Inst.C.E., "Heavy Oil Engines." Four Lectures.

April 29, May 6, 13, 20.

JUVENILE LECTURES.

Wednesday afternoons, at 5 o'clock:—

CHARLES VERNON BOYS, F.R.S., "Soap Bubbles." Two Lectures.

January 3, 10.

THE ROYAL SOCIETY OF ARTS.*

By SIR HENRY TRUEMAN WOOD, M.A.,
Secretary of the Society.

V.—THE SOCIETY AND AGRICULTURE.
(1754–1830.)

When the Society of Arts first included agriculture among its objects, but little real advance had been made on mediæval methods. Yet new ideas were in the air, and as far back as the very beginning of the eighteenth century the commencement of the change can be discerned which was soon to abolish the old order of things, and to modify in the course of a comparatively short period the ancient system which had sufficed for so many generations. The time was favourable for improvement, and some central authority was badly needed to co-ordinate and direct the scattered efforts which were being made in England, Scotland, and Ireland to bring about an improved system of husbandry. As a matter of fact, side by side with the industrial revolution, an agricultural revolution was in progress, and the two great movements had their reciprocal influences upon each other. The development of the factory system was at once drawing the agricultural population into the towns, and was depriving them of their ancient means of livelihood by the destruction of domestic industry, while the growth of the urban population demanded more abundant food supplies, and thus necessitated improved systems of cultivation, by which alone those supplies could be provided. The old open-field system had by no means come to an end by the middle of the century, but the system of enclosure and the division of previously common land had made sufficient progress to render possible the existence of those large farms on which alone any attempt at scientific agriculture could be made. While the arable land of a village was divided up afresh every year among the commoners to whom it belonged, none of its temporary owners could do much, if anything, for its permanent improvement, and anything in the nature of rotation of crops was impossible when the strips of land changed proprietors at short intervals. Again, it was only on farms of considerable size that experiments in new methods of cultivation could be made, and there were many ready to try such experiments, for scientific agriculture had already made some advance. The system of a proper rotation of crops had been invented, and was being rapidly extended. New crops had been introduced, which alone made rotation possible. Of these the most important was the turnip, but clover and lucerne had also not long been added to the list. The new ideas promulgated by Jethro Tull, of the highest practical value, if based on erroneous theory, were attracting attention. Bakewell had just commenced his experiments in stock-breeding by the help of careful and judicious selection. Such were some of the main elements of the agrarian revolution in the successful development of which the Society of Arts was certainly one of the main factors.

In the original scheme of the Society agriculture was not included, and when the

* The previous articles of the series appeared in the *Journals* of June 9th and 16th, and September 22nd and 29th.

suggestion was made to Shipley that it should be so included, he met it with the not very conclusive objection that all the awards would be taken in those districts of the country in which the greatest progress had been made. Indeed, in the first list of premiums, that of 1756, there is no prize offered for any agricultural subject, unless, indeed, madder be considered as such. But this was soon altered. In the next list (1758) there are a number of prizes offered for agricultural improvements, and from that date onwards for the next fifty years agriculture occupied an important, indeed the most important, part in the lists of premiums.

In fact, the Society was for long mainly an agricultural society, and by far the most important one in the kingdom. There were some provincial societies in existence when it was founded, and others were soon formed, but it was in communication with all of them, and it was the centre to which information was sent, and from which it was distributed to the various parts of the kingdom.

In agriculture, as in the other divisions of its work, the fundamental idea which directed the Society's efforts was the offering of rewards, either pecuniary or honorary, for the successful carrying out of its objects. These rewards varied greatly in value, and they were carried on from year to year until the end sought for appeared to have been attained, and the new industry, or method of tillage, or crop, or whatever it might be, was so firmly established as not to require further assistance or protection. The scope of the prizes offered under the direction of the Committee on Agriculture was very wide. It included the successful rearing of all sorts of crops, even of such well-known crops as wheat, barley, oats and rye; the introduction of new forage plants and of roots for cattle-feeding; the suggestion of new methods of husbandry, their discussion and the supply of information about them; the invention of new implements or appliances and the improvement of old ones; information on the use and value of manures; suggestions on soil analysis; the treatment of cattle and sheep, and in fact any advance or improvement calculated to aid the progress of agricultural knowledge and practice. An annual list of suggested subjects was published, but the rewards were by no means confined to these lists, and the Society was quite as ready to consider and reward any useful proposal submitted to it from outside, as it was to award the prizes enumerated in its own catalogues.

The lists were prepared with great care, and modified from year to year, though we find the same offer repeated time after time, sometimes over a long period, even though large amounts had already been paid away among successful competitors, for it is to be remembered that the premiums were not, as a rule, in the nature of prizes to be taken once for all, but rather as grants-in-aid, to be repeated as long as there seemed to be any need for such assistance.

The value of the help thus rendered to agricultural progress is made evident by much contemporary testimony. In such a matter there is no higher authority than Arthur Young, and he, in his "Farmers' Letters,"* speaks in terms of high commendation of the Society's work, and comments on the premiums offered for 1766. Arthur Young was a member of the Society from 1769 till his death in 1820, and in 1774 he became Chairman of the Committee on Agriculture. He was therefore thoroughly well acquainted with the Society's work, and he was also a very outspoken person, and very candid in the expression of his opinions, so that any laudatory expressions from him are likely to be well justified. But, while on the whole he appreciated the Society's action, he thought that it might be improved upon, if, instead of merely offering prizes for successful agricultural experiments, they undertook the direction of such experiments themselves by selecting a number of intelligent farmers who could be trusted to carry out the work, and subsidised them, giving them also additional premiums in proportion to the manner in which the work was carried out.

There cannot be much doubt that a great deal of useful information might have been accumulated by following out Young's suggestions, though it might have been difficult to carry them into effect without more expense in the way of supervision than he contemplated. If they could have secured Young's services and got him to undertake the supervision of a scheme such as he suggested, the difficulties might have been overcome, but in the absence of a thoroughly competent expert to control the whole working of such experiments, it is difficult to see how they could have succeeded. In Mr. Wynn Baker the Dublin Society had such an expert, and they wisely placed considerable funds at his disposal, with very satisfactory results. It may, however, be observed that

* Letter VI., Vol. I. p. 214. The edition to which reference is made is the third, published in 1771. The first edition was published in 1768, the second in 1769.

during the many years while Young was Secretary to the Board of Agriculture after 1793, he never seems to have made any attempt to carry out the excellent suggestions he proffered for the benefit of the Society of Arts.

But while the distribution of rewards for successful experiment or invention was the principal device by which the Society endeavoured to attain its objects, it must not be thought that it was the only one. The diffusion of information by means of its publications was one almost equally important method, though its value was not recognised for some time. At first in the publications in which its proceedings were reported, to begin with in the *Museum Rusticum*, afterwards in Dossie's "Memoirs of Agriculture,"* and eventually in its regular *Transactions*, it recorded and disseminated a vast deal of agricultural information, and in this way aided most effectually the progress of agricultural science and practice. Another important agency was its "Repertory of Inventions," which, during the first half century of its existence, contained an excellent collection of models of agricultural implements. This was opened freely to the public, and by its means an opportunity of examining the latest implements and appliances was afforded to all who cared to profit by it. On occasion also the Society purchased machines and models in foreign countries, and obtained from abroad plants and seeds, which were distributed to the members.

When the Society began its agricultural operations one of the greatest difficulties which pressed upon the farmer was the need for a supply of winter fodder. He was then entirely dependent upon a meagre provision of hay, and that not of the best quality. The use of turnips for cattle food was only gradually making way, for although Arthur Young,† writing about 1769, speaks of "vast fields" of turnips in Norfolk, it is probable that the epithet was only used in comparison with the scanty crops grown in other counties, and, indeed, the remark was made by way of drawing attention to the small amount of the root which was actually being cultivated. The use of oil-cake for cattle food was hardly thought of. The editor of the *Museum Rusticum*,‡ in a note on a correspondent's article on feeding cattle, says that in Flanders the refuse from oil-mills had been given to cattle of all kinds, and, in another similar note, in the same volume,* he adds that oil-cake, from which the oil has been expressed, had been tried with success in England as well as in Flanders. It had not really come into use, however, for in the first volume of the Society's *Transactions* (1783), in connection with the offer of a prize for oil from cotton-seed, it was suggested that the seed, after the extraction of the oil, might form a useful food for cattle.

One of the first things taken up by the Society was the production of grass seed, and Arthur Young thought this a matter of the highest importance. Previously the only grass seed used was the sweepings of the hay-lofts, in which all sorts of seeds were mixed together, with a large proportion of seeds of undesirable weeds. The Society offered in 1762 several prizes for clean grass seed, giving instructions as to the way in which grass should be specially cultivated for seed, and promising also to find a market in London for any parcels of seed of a suitable character. Other prizes were offered for hand-picked grass seed, provided the seed was all of the same species.

Awards were also offered and awarded for the growth of crops considered to be suitable for winter or early spring food, including burnet, borecole, sainfoin, lucerne, winter clover, buckwheat, cabbages, beans, vetches, etc. These crops were then little known and sparsely cultivated.

The ordinary field turnip had been known for less than a century; it had been introduced some time—it is not really known by whom—near the end of the seventeenth century. Arthur Young gives the credit of its introduction to Jethro Tull (1674–1741), the father of scientific agriculture in England, but in this he was certainly mistaken. Both sheep and cattle were folded upon turnips, which were used to a very limited extent for winter food. Carrots and also parsnips were grown for cattle food, but their growth had hardly got beyond the experimental stage. Potatoes were only to be found in gardens, and were not used for cattle† until some time in the early part of

† Although the potato was introduced into Ireland by John Hawkins in 1565, and into England by Sir Francis Drake in 1585, it had attracted so little attention, that in 1663 the Royal Society urged such of its Fellows as possessed land to plant potatoes, and to persuade their friends to do the same, in order to alleviate the distress that would accompany a scarcity of food. Nothing, however, seems to have come of this recommendation, and so little was thought of the potato for some years after that Bradley ("Historia Plantarum Succulentarum," 1716-1727) speaks of it as of little note, and in the "Complete Gardener" of London and Wise (1719) it is not mentioned at all.

the century. In 1779 Arthur Young received a gold medal for an account of the "Clustered Potatoe." This was one of the two medals* he had from the Society. For the cultivation of all these roots and for information as to the best methods of cultivating them, the Society offered many rewards, extending over a long series of years. The list also, at a later date (1805), included beet, on account of its use for cattle food, not for its sugar-producing qualities, which were a much later discovery.

All agricultural authorities are agreed as to the great part played by the introduction of the turnip into British agriculture. Without it any proper rotation of crops would have been impossible, and, until it was available for the purpose of feeding stock through the winter, farmers and graziers were in bad seasons forced to kill their stock cattle and salt the meat down for winter use. Hence for centuries the only meat generally available in the winter was salt meat. The extended cultivation of the turnip rendered possible the supply of butchers' meat in winter time to the rapidly increasing population, and so this modest vegetable was not only a prime factor in the agrarian revolution, but a valuable if overlooked agent in the progress of industrial development, and, indeed, of civilisation.

In encouraging the cultivation of the turnip the Society did its full share. Many pages in many volumes of the *Transactions* are devoted to the discussion of the best methods of growing it, and to dissertations upon the comparative advantages of drill and broadcast husbandry.

But besides encouraging the growth of crops already known, if not extensively cultivated, the Society was directly the means of introducing into England two roots which are now as important as the turnip itself—the swede and the mangel-wurzel.

Among the forage plants which had been introduced into England about this time was the turnip-cabbage (*Brassica oleracea caulorapa*), or chou-rave, now known under its German name of Kohl-rabi. This plant, according to Young, was brought into England from Carniola in 1749 by the Rev. Mr. Haste, Canon of Windsor, well known at the time as the author of "Essays on Husbandry." It had attracted a good deal of attention, and was to some extent being cultivated. It was the subject of two long articles in the *Museum Rusticum* in 1766,† which gives two good illustrations of the plant. It appeared to the Society that this little-known plant was well worth further attention, and amongst the premiums for 1867 was one for its cultivation. The offer attracted the notice of John Reynolds, a farmer of Kent, and he, being unable to obtain a supply of the seed in England, sent to Holland for some. The plants grown from this seed proved to be quite different from what he expected, and turned out to have large roots resembling that of the turnip, instead of the succulent stem of the Kohl-rabi. As a matter of fact he had been supplied with seeds of the Swedish turnip (*Brassica campestris rutabaga*); and this was the first introduction of the now well-known swede, then cultivated to some extent in Sweden, Russia, and Northern Germany, but absolutely unknown in England. This unknown plant he christened "the turnip-rooted cabbage," a not very suitable title, for though both it and the field turnip (*Brassica rapa*) are members of the cabbage family (*Brassicaceæ*) the swede is not a bit more like a cabbage than is the ordinary turnip. He grew a small crop of it and sent specimens to the Society. The value of the introduction was at once recognised, and a grant was made to Reynolds of £50. Seed from his plants was also distributed among the members for trial, and the new crop was recommended for its hardy nature and its capacity for standing frost. A full account of his experiments is given by Dossie,* and this is supplemented by some further observations on the nature and character of the plant, apparently written by Dossie himself. The full information on the subject first published by the Society attracted a good deal of attention, and for many years the Society continued to offer and present rewards for persons growing the "turnip-rooted cabbage," and for those who supplied information as to the best methods of securing large crops of it. The similarity of the two names evidently caused confusion, for appended to the offer of one of the prizes in 1769 is a note: "The plant here called the Turnep-rooted cabbage is not the same with the Turnep Cabbage, but that kind newly introduced into this country." For a long time it is only mentioned under this name in the Premium lists and *Transactions* (though it is said also to have been known as "Reynolds's Turnip"), but eventually the title seems to have been dropped, and the now well-known name of swede,† applied to

* He also received two small prizes in 1765 and 1767 for growing madder.

† Vol. VI. pp. 46, 220.

* Vol. I. p. 419.

† In "Les Plantes Potagères" (Vilmorin - Andrieux et Cie, Paris, 1883, p. 141) the authors, under the heading of "Choux-Navets," give as synonyms: Chou-rave en terre,

the plant from the country of its origin, came into use.

The introduction of the mangel-wurzel came a little later. In 1786 some seeds of the *Racine de disette*, or "root of scarcity," were given by Sir Richard Jebb—a very well-known physician at the time, who died in the following year—to the Secretary of the Society, Dr. More, by whom they were distributed to some of the members. This "root of scarcity"—soon better known by its German name "mangold-wurzel"* —according to a statement made by Jebb's executor, Granville Sharpe, had been discovered by a French cultivator in search of a new forage plant. It was suggested that both the leaves and the roots might serve as a table vegetable.

Amongst the members who received samples of the seed was J. C. Lettsom. He grew the seeds, and tried the leaves cooked like a cabbage and also the root, but does not seem to have greatly appreciated their flavour, though he thought that, as its name implied, the vegetable might be useful in times of scarcity. He was much interested in the new plant, which he considered much more suitable as a food for cattle than for human beings, and translated a treatise on it by the Abbé Commerell, which was published in London in 1787 under the name of "An Account of Mangel-wurzel." The particulars here stated are taken from the preface to that book. The value of the plant does not seem to have been recognised at first, and it was some time before it received the attention it deserved. No special reference to it appears in the Society's lists until 1814, when a gold medal was awarded to Leonard Phillips, "Portsmouth Road, beyond Vauxhall Turnpike," for "the growth of mangel-wurzel."

The implements then available for the farmer's use were very few and of a very inferior sort. For tillage there was the plough, varying in character in different districts of England, and the harrow. The horse-hoe* had not long been introduced, and the drill was known but rarely used. The crops were all got in by hand, the scythe, the sickle and the reaping-hook being the only known implements, as for centuries before. When the corn was harvested the only means for separating the grain from the straw was by the use of the flail.

This state of things, however, was very soon to be altered. In all industrial processes the substitution of mechanical power for hand labour was making rapid progress, and the change was beginning to be felt in agriculture as well as in manufactures. As the writer of the article on agriculture in the "Encyclopædia Britannica" puts it: "The quarter of a century immediately following 1760 is memorable in our agricultural annals for the introduction of various important improvements." And the introduction of these improvements was mainly due to the efforts of the Society of Arts. As evidence of this, another similar authority may be quoted, for in "Rees' Cyclopædia" (edition of 1819) the writer of the corresponding article, referring to the work of the Society, tells us that "a vast variety of different machines for facilitating the practice of agriculture have been invented and presented to the public, in consequence of the large premiums and bounties which have been offered" by it.

To trace in detail the history of all the improvements in agricultural implements and machinery which were due, in whole or in part, to the rewards paid by the Society, to the suggestions it put forward, or to the information it collected, would be a long and difficult task, and the result would not be either interesting or valuable, but it may safely be asserted that of all the implements new and old used by the farmer during the fifty or sixty years from 1760 onwards (not including, of course, ordinary hand tools) there was not one which was not either introduced or improved in consequence of the Society's exertions and influence.

Even the ordinary plough underwent a larger amount of development during this period than in the century or more preceding, not so much in consequence of any direct offer of premiums for improvements, as because the Society was always ready to take up and reward any

chou turnep. Noms étrangers:—*Anglais:* Turnip-rooted cabbage, swede, Swedish turnip; *Allemand:* Kohlrabe, etc.

"The Vegetable Garden"—a translation (1905) by W. Robinson of the above—(p. 166), under the heading, "Turnip-rooted cabbage (Swedish turnip); French, chou-navet; German, Kohlrabi," etc., says: "The varieties of turnip-rooted cabbages differ from the Kohlrabi (chou-rave) in that, instead of having the stem swollen over-ground, they produce, partially buried in the soil, a thick root which is about as long as it is broad, resembling a huge turnip, and of which the flesh is yellow in the Swedish turnips and white in the other kinds. The characters of the leaves and flowers of these plants indicate plainly that they are true cabbages. . . . The Swedish or turnip-rooted cabbage is an excellent vegetable."

In Vol. XV. of the *Transactions* (1797) it is mentioned that Lord Romney had presented the Society with "a quantity of Swedish Turnep-Seed."

* Mangel-wurzel is a beet, its botanical name being *Beta hybrida*. On its introduction it was known as *Beta vulgaris macrorhiza*.

* The date of the introduction of the horse-hoe into this country does not seem to be known. It was probably first employed in the vineyards of Italy and France, and that long before it was known here.

ingenious advance in this or any other implement. Such changes as were effected were mainly in detail. The frame was made lighter and better balanced; iron was substituted for wood in many parts of the frame, etc.; the shape of the share, coulter, mould-board, and other details were improved; the draught was lessened, and—a very important matter—the price was lowered, so that, as a general result, many of the ploughs commended and rewarded by the Society became popular, and are said to have sold well. All these improvements, however, were the result of rule-of-thumb experiment, and it was not until 1839, when the question was taken up by the Royal Agricultural Society, that any scientific investigation was really made into the principles which should govern the construction of ploughs. In that year, Mr. Philip Pusey published, in the first volume of the R.A.S. Journal (p. 219), the results of an experimental inquiry on draught in ploughing made by him, and the dynamometrical tests which he conducted upon the different sorts of ploughs had an immediate effect in improving plough construction.

The Society also, besides improving the character of the ordinary plough, did much to introduce ploughs of special types, applicable for trenching, draining and subsoiling, paring and scarifying, etc.

The drill had been invented by the enthusiastic and eccentric Jethro Tull in 1707, and its use advocated in his remarkable book, "Horse-hoeing Husbandry," in 1731, but it had not really come into use except to a very limited extent. Dossie * is responsible for the statement that Tull "only started the notion. The practice was very little pursued till the Society awakened the public attention to it by their premiums." That this statement was correct seems indisputable. The offer of a gold medal in 1762 for the best set of experiments and observations on the comparative merits of drill and broadcast husbandry produced a series of communications from Sir Digby Legard, extending from 1763 to 1768, and giving the result of a very careful series of tests carried on during those and previous years in Yorkshire, and also one from the Rev. Mr. Lowther, giving an account of similar experiments in Cumberland in or before 1763. Both these gentlemen received a gold medal, and their papers were the first of a long series of communications on the subject, which eventually established the value of the then novel system.

* Vol. I. p. 73.

Tull himself, in the various editions of his well-known book,* describes his drill in full detail and with abundant illustration. It must have been an excellent piece of apparatus, well suited for its work, and in its mechanical details considerably in advance of most contemporary machinery. Very probably its actual construction may have been deficient, and it was less effective in operation than appears on paper, for in those days the means of accurate machine construction were sadly lacking. But by all accounts, it was a good practical implement, and quite effective in operation.

Sir Digby Legard speaks favourably of the original machine, though he suggests certain additions and seems to have made some. Still it was not considered satisfactory, and prizes were, therefore, offered in 1761 for "drill ploughs which should cut several furrows, deposit the seed, and cover the seed with earth at one operation." The earliest award under this head was to the Rev. H. Gainsborough, a brother of the great painter, in 1766. He received £30 for a "drill plough." Other prizes followed in 1770, 1771, 1775, and for many years later.† The earliest patents for drills are those granted to Proud (in 1781) and to Cooke (in 1783). After this date the patents are numerous; there were about ten others in the next eight years.

Cooke's patent drill was submitted to the Society in 1787, and was commended, not—as the subject of a patent—being eligible for reward. Two reports, speaking well of the apparatus, were printed in the *Transactions*.‡

Still, though the advantages of the drill were recognised, and the machine itself became well-known, it was very many years before its use became general. As late as 1839, Mr. Pusey, in his inaugural address to the then newly-founded Royal Agricultural Society, addressing an assembly of farmers, thought it necessary to describe the drill as a machine "by which the seed is laid in regular rows," and mentioned that "it was not very much used, although it had lately become frequent."

* The book was first issued in an incomplete form in 1731. The first complete edition appeared in 1733. A further edition, with additions, was published in 1739. After Tull's death in 1740, other editions were issued, 1751, etc. Cobbett published an edition, with much of the original omitted, in 1822. An interesting account of Tull and his work, by the late Earl Cathcart, appears in the *Journal of the Royal Agricultural Society*, 1891, Third Series, Vol. II. p. 1.

† The best, among the early inventions, seem to have been those of Gale and Craik, both Scotchmen, to whom gold medals were awarded in 1771.

‡ Vol. V. p. 71, *et seq.* A description, with a drawing, will be found in the patent specification.

Another implement, which, though not invented by Jethro Tull, was the subject of his earnest advocacy, was the horse-hoe. A clumsy-looking implement is figured and described in the *Museum Rusticum*,* and various prizes for horse-hoes were awarded at different times by the Society. The earliest of these was a gold medal to the Rev. Mr. Hewett, in 1771. A number of awards were also made for harrows and for rollers, including a "spiky roller" in 1766.† In 1801 a silver medal was awarded to W. Lester for an implement "named by him a cultivator." The implement, as described and figured in the *Transactions*, is typical of the older form of cultivator before its modern improvements and alterations. It has vertical tines, slightly curved at the points. As is well known, the modern cultivator has various forms, is applied to many purposes, and is known by several names. It had, as originally designed, vertical coulters or tines, and was used for breaking up unreclaimed or fallow land. Probably the first description of it is that contained in Lester's communication to the *Transactions*.‡

In its efforts to encourage the invention of a reaping machine, the Society was certainly much less successful, and this chapter of the Society's history is decidedly less satisfactory to its historian than those which deal with the other agricultural implements.

In the premium list for 1774 appears the first offer of a reward for a machine capable of reaping corn, and this offer was continued with certain variations up to 1820, a period of forty-six years. During all this long period not a single award appears to have been made, and this is really inexplicable, because a number of inventions were brought out during this period, and several were at different times submitted to the Society. Most of these were impracticable and useless, but there was certainly one which was beyond much question the origin of the modern reaper. In the year 1812 Earl Percy sent to the Society a model of a machine made by John Common of Denwick, Northumberland, together with a certificate from John Thew and Thomas Appleby that the machine had successfully cut a patch of ripe oats. The apparatus is described, not very fully, in the committee minutes of April 15th; but the description is sufficient to show that the principal feature of the machine was a set of angular knives mounted on a horizontal bar, to which reciprocating motion was given by a crank, the corn being guided to the cutters by means of spikes or "fingers." This is precisely the mechanism of all existing reapers. Previous inventions, and some of a later date, used reciprocating blades or revolving scythes, but none of these gave the shearing or drawing cut which alone answers for cutting corn. The verdict of the committee was that the invention was incomplete, and they did not recommend it for an award—a verdict which simply shows that the committee as then constituted was unfortunately incapable of appreciating a very great and important invention, the very novelty of which was probably too great for them to realise its value.

The history of the invention is given in full detail in an article and some letters contained in the *Journal* of the Society for 1878.* From these it appears that Common co-operated with Ogle, who was the inventor of an unsuccessful reaping machine of the rotating scythe class, and that he employed one Brown to make certain castings for him, the patterns for which Brown in 1830 took to America. There he either constructed a machine, and disposed of it to McCormick, or gave the patterns to McCormick, and provided him with information from which McCormick was able to construct a machine. At all events there seems no doubt whatever that Common's reaper was the original of the machine brought out by McCormick, and exhibited by him in the American section of the 1851 Exhibition as his own. In consequence McCormick had for long the credit of being the inventor of the modern harvester until the true facts were brought out, and the invention attributed to its real author, John Common. At the same time it should not be forgotten that while the evidence seems to disprove McCormick's claim to be an original inventor, it does not in any way diminish the value of his public services in the introduction of the reaping machine. It often needs two men for the success of an invention, one to invent and one to publish. Generally the second man gets the profit, and it is not always certain that he may not deserve it; he does not generally get the

* Vol. VI. (1766) p. 402.

† *Museum Rusticum*, Vol. VI. p. 371.

‡ Vol. XIX. p. 142. This, however, is not the first use of the term, for in the list of implements in the Society's Repertory in 1783, a "cultivator" is mentioned. Murray's Dictionary gives a still earlier use in a translation of Duhamel's Husbandry, 1762.

* Vol. XXVI. pp. 369, 419, and 479. The information contained in these pages, with some further additions, was republished in a little book in 1907 by R. F. J. Common, the grandson of the inventor.

credit, though there seems no reason why he should not fairly claim a share of it. John Common's first machine appears to have been made about the year 1803, and to have grown out of a suggestion made by Ogle. Two other machines were made by him—one about 1811, and the third in 1812.

It makes it the more remarkable that Common's reaping machine was never rewarded by the Society that later, in 1818, he received a gold medal for a turnip drill, and later still, in 1844, a silver medal for a plan of putting new roots to old trees, neither of them comparable with his really great invention of the reaping machine. John Common was living in 1860, and a letter of his of that date is published in one of the *Journals* above quoted. John Thew, one of the witnesses of the trial above mentioned, was living in 1878, and was able at that date to confirm his former statements.

Nor was the Society more successful with another inventor of an original reaper, the Rev. Patrick Bell, whose machine was submitted to the Society in 1830, but was not rewarded on the ground that the description of the machine, which was an excellent one, had brought it sufficiently before the public, and that it did not therefore require the Society's aid to bring it into notice. Bell, who was then a young man studying for the ministry at the University of St. Andrews, invented his reaper in 1827, and it was tried the following year on a farm in Perthshire belonging to his brother, George Bell. He appears only to have constructed one machine, which worked regularly from about 1828 to 1868, when it was purchased for the Museum of the Patent Office. It is now in the Mechanical Engineering collection of the Victoria and Albert Museum.* A full account of his invention was given by Dr. Bell at the meeting of the British Association at Dundee in 1867, but unfortunately only a brief report of the paper appears in the Proceedings of the Association. Bell's machine was never patented, but later on, after attention had been drawn to McCormick's machine in the 1851 Exhibition, many machines were made after his model, and came into extensive use.†

Unlike most of the new agricultural implements, the reaping machine, when once attention had been drawn to it, came rapidly into use. Morton, in his "Cyclopædia of Agriculture," writing in 1851, in his article on "Harvesting Machines," refers briefly to Bell and McCormick, and says: "Notwithstanding all the ingenuity, however, that has hitherto been applied to the subject, reaping has been, and no doubt for many years, as we have said, will continue to be, a manual operation." In the same volume, in a later article on "Reaping Machines," which must have been written in or before 1855, he recants his views of four years before and describes at considerable length, with illustrations, an improved form of Bell's machine, and also those made by Hussey and by McCormick.

The earliest reference to a threshing machine must certainly be contained in the grant of Letters Patent in 1636 to Sir John Christopher Berg, for an "invencion to bee agitated by winde, water or horses for the cleane threshing of corne," but about this no further information exists, and the first machine which is known to have been used for the purpose of threshing corn was that patented by Michael Menzies in 1734. No specification was filed, and the only information afforded by the terms of the grant is that the machine "threshes with common swipples."* A description, however, is given by Maxwell in the *Transactions* of the old Scottish Society of Improvers in the Knowledge of Agriculture, which he published in 1743. This machine appears to have consisted of a number of flails, probably mounted on a central shaft or drum, which was either operated by hand or "by means of a great water-wheel and triddles." Though Maxwell recommends it, it does not appear that Menzies' machine was ever much used, and the first practical threshing machine was that of Andrew Meikle, patented in 1788, and stated to have been working in 1798 in Clackmannanshire. From the description in the patent specification it is evident that this machine may be regarded as the precursor of the modern threshing machines, since the principle on which it was constructed is really that which has been elaborated in the modern machine—a revolving drum with what he called "scutchers" working under a curved shield This apparatus soon came into practical use, and it was later largely improved upon, until it

* The excellent catalogue of this collection contains (p. 227, edition 1908) a brief historical note on harvesting machines and (p. 232, Nos. 1515 and 1516) a description of Bell's machine (No. 1515 is the original somewhat altered, and No. 1516 is a model of the original). There are also models and descriptions (pp. 232 and 233, Nos. 1,517, 1,518, and 1,519) of McCormick's reaper. No reference is made to Common, and it is to be hoped that the omission may be rectified in any future reprints.

† Much information about the earliest attempts to make reaping machines will be found in the "Appendix to the Specifications of English Patents for Reaping Machines," by B. Woodcroft, published by the Patent Office. This work is now seldom to be met with.

* Swipple is a north-country name for a flail, or the head of a flail.

developed into the apparatus now in common use.

The first award made by the Society for a threshing machine was in 1761, when £15 was given to John Lloyd. No description of this appears to be extant. A machine "for threshing and winnowing corn," for which fifty guineas was awarded in 1769 to John Evers, is highly commended by Dossie,* but it appears to have been rather a clumsy apparatus, and must have absorbed a great deal of power. The corn was spread on a revolving floor, and thus brought under the action of "a row of a kind of flails." This anticipated Meikle's by some twenty years, but was certainly inferior and worked on a very different principle.

Four years before this, in 1765, a bounty of £15 had been awarded to a Mr. Harvey for a threshing machine "used in Connecticut." From the note upon it in the manuscript minutes of the Committee on Agriculture, it consisted of a cone with longitudinal ribs revolving from a fixed centre over a floor on which the corn was laid. Nothing more is known of the apparatus.

After this the subject was neglected till 1801, when a gold medal was offered for a threshing machine which should be an improvement on any then used. This was awarded in 1810 to H. P. Lee. His machine consisted of four vanes or beaters on a central shaft working in a concave. Motion was given by a horse-gear through spur gearing to the shaft. A special merit of the apparatus seems to have been the high speed at which it could be driven.

The earliest suggestion of the use of apparatus for cutting or chopping straw for fodder is probably contained in the first volume of the *Museum Rusticum* (1761), p. 258, and further details are given in the volumes for 1765 and 1766.† In the first of these a "cutting-box" for fodder is described as a novelty, and in the second a fuller account is given with illustrations. It is simply the old form of chaff-cutter, common enough fifty years ago, in which the straw or straw and hay is pushed along a trough by hand, and cut by a hinged blade working across the end of the trough, the straw, etc., being held down, while the cut is being made, by a presser worked by the foot or otherwise. The machine is spoken of as something quite new and useful, and from the description it appears that the idea of using chopped straw for the food of cattle and horses was previously unknown.

* Vol. I. p. 86.

† Vol. V. p. 208, and Vol. VI. p. 8.

In 1769, 1770 and 1774, rewards were given for three machines for cutting straw, but no description of any of them has been discovered. It is very possible that one or other of these was the apparatus of the *Museum Rusticum.* In 1786 a reward of twenty guineas was given to James Pike, a watchmaker of Newton Abbot, for a chaff-cutter, which, though, from the illustrations in the *Transactions* * rather a clumsy apparatus, is probably the original form of the modern chaff-cutter, and is certainly a great improvement on the old form, with its hinged knife-blade worked by hand, and a hand-feed. In it a wheel or disc, carrying a single curved radial blade, revolves across the end of a trough, along which the fodder is fed by rollers operated by a worm and spur-wheels from the axle of the wheel. This is merely an elementary form of the present chaff-cutter, which is improved in details and in construction, but is precisely the same in principle. Eight years later, James Cooke patented the same idea, but fitted three knives on his fly-wheel, a great but obvious improvement. He also added a fixed blade, against which the revolving blades acted. Later inventors made the feed intermittent by means of a worm of varying pitch, or by driving the gearing through a wheel with only one tooth on each side, and improved the construction generally, but the chaff-cutter now universally known is only an improved version of those of Pike and Cooke.

The offer of a prize in 1766 for a machine for slicing turnips was condemned by Arthur Young† as rather trivial, but the apparatus sent in in answer to the offer was the first of a long series of inventions upon which a vast amount of ingenuity has been spent. The turnip-cutter of the present day is the result of the best part of a century's work, and it is not very long since the apparatus has been brought to perfection so that it will not only slice the roots but will cut them into "fingers" of a convenient size and shape for the food of cattle. In the following year, 1767, two rewards were given, £20 to James Edgell, and ten guineas to William Bailey. Dossie, who speaks well of James Edgell's machine, does not describe its action, but it evidently sliced the roots only, without any further division. In succeeding years other machines were commended or rewarded by the Society, but to judge by the records of the Patent Office it was very long before attention was really directed to this class of apparatus. The

* Vol. V. p. 62.

† "Farmer's Letters," Vol. I. (Second Edition, 1771) p. 234.

earliest patent for a turnip-cutter was granted in 1803, and it was not till 1834 that Gardner's machine, which afterwards came largely into use, was invented. After this there were numerous improvements.

The use of manures was hardly known, and, indeed, could hardly be known, so long as the open-field system endured. The practice of applying marl had been lately introduced in Norfolk, and a writer in the *Museum Rusticum* (Vol. II. p. 132) states that the Suffolk farmers were in the habit of using "cragg" containing "remains of marine shells." Farmyard manure was, of course, available, and the manuring of fields by folding sheep and cattle upon them was also practised. Lime was used to a very limited extent, and so were ashes. On the sea-coast, seaweed seems to have been utilised. Town nightsoil was employed in some localities where it was available, and the system of paring the surface and burning it was also found serviceable. Young, writing about 1769, mentions that oil-cake was imported from Holland for use as a manure at a cost of 15*s*. an acre. Its value as a cattle food was not generally known, though, as previously mentioned, such application has been proposed, and indeed tried.

In 1758 a prize was offered for a dissertation on "The Nature and Operation of Manures," the following being specified: "soot, coal-ashes, wood-ashes, lime, and nightsoil." The offer was continued in the same terms for very many years, "bones" being added to the list in 1817, and "salt" in 1825. After this date the prize was discontinued. During its continuance a good many awards were made, and various papers, none, perhaps, of very great value, were published in the *Transactions*.

The same list (that of 1758), which contains the first reference to manures, includes also a premium for a dissertation on "Soils and their natures." This was afterwards developed into an offer of a gold medal for "ascertaining the component parts of arable land," by a series of experiments. Detailed instructions were laid down as to the nature of the analysis of the soil, and practical proof was demanded of the improvement of sterile soil, by the addition of such "components" as appeared to be lacking, and the absence of which might be assumed to be the cause of the sterility. A good deal of information was supplied to the Society from time to time, and published in the *Transactions*, but it does not appear that the exhaustive series of experiments laid down by the Society were ever carried out in their entirety. The proposal, however, is not without interest, as marking the commencement of agricultural chemistry, which may be said to have first taken definite form in England when Sir Humphry Davy, after delivering a course of lectures in 1803 on the "Connection of Chemistry with Vegetable Physiology" for the Board of Agriculture, had been appointed by the Board Professor of Chemical Agriculture, with the duty—besides that of delivering annual courses of lectures—of analysing soils and manures at fixed fees for those who required such work. Davy had been preceded by Duhamel in France, where science —especially chemical science—was ahead of English knowledge; but the work of Davy soon surpassed that of his foreign rivals.*

The question of stock-raising never seems to have received any attention at all from the Society, and this is rather remarkable, because the successful experiments of Bakewell —commenced just about the time the Society was established—had attracted a great deal of attention, and had been followed up by numerous breeders of stock, cattle as well as sheep, all over the country. He was the first to indicate and to emphasise the necessity for proper selection in breeding, and the principles he laid down had the greatest possible effect in improving the character of British stock. George III. was an enthusiastic farmer and breeder, and many of the great landowners were devoting themselves to what was really the scientific raising of new breeds of sheep and cattle. All this, however, seems to have been regarded as outside the Society's province. There are occasional papers in the *Transactions* on feeding cattle, horses and sheep, on treating their various illnesses, etc. Arthur Young had a gold medal in 1769 (his first medal from the Society) for his system of fattening hogs, and from time to time a few unimportant premiums of a like nature were offered and bestowed; but, on the whole, the Society appears to have left this important subject severely alone.

Very many other objects were suggested in the Society's lists, or received premiums when submitted to the Society's notice. One of the most important of these was the reclamation of land from the sea, and there is a long list of those who received medals for such additions to the cultivable area in many places on the coast. The cultivation and improvement of waste land, the proper rotation of crops on

* See a life of Davy," by H. B. Wheatley, *Journal of the Royal Agricultural Society*, Vol. LXV. (1904) p. 1; also "Humphry Davy," by Sir Edward Thorpe (1896), pp. 94-99.

different soils, irrigation, the destruction of insect pests, methods of marking sheep so as to avoid the use of tar, harvesting crops in wet weather, the draining of land, were all matters to which attention was directed, and on which, from 1760 till about 1830, considerable amounts of money were expended. Bee culture was at one time (from 1760 to 1770) one of the minor industries that was warmly supported, and a large number of small prizes were given for keeping bees, and for producing wax and honey. Beeswax was then a more important article than it is now, as it was practically the only material available for the best candles.

By the end of the second decade of the nineteenth century the value and importance of the Society's agricultural work had greatly fallen off. In the preface to the volume of *Transactions* for 1819 (Vol. XXXVII.) we find a suggestion that "The object of the Society in the early and enlightened liberality with which they fostered the most important of the practical arts, agriculture, has, for the most part, been accomplished." The fact probably was that while the prosperity of the Society was at this time waning, the attention of its most active supporters was directed to other subjects than agriculture, and it did not appeal specially to them. At all events, from this time forward the Society was content for the most part to leave to other agencies the direction of agricultural progress. After this date, though occasional rewards were given for agricultural implements, they were neither numerous nor important. A few years later (in 1827), in place of the various detailed descriptions of apparatus which were required, the premium list contains only a general offer of rewards for "machines for performing any agricultural operations," and eventually the prizes seem to lapse altogether. The work had indeed been taken up by another agency. The "Board of Agriculture" had been established in 1793, and had carried on a not very valuable life till 1822. It was not really a Government department, but a sort of independent commission, enjoying a subsidy of £3,000 a year from the State. It had the good fortune to secure Arthur Young as its secretary, and if he had had a free hand it might have effected more useful work; but for the first part of his tenure of his office he was hampered by the proceedings of the chairman, Sir John Sinclair, whose influence had obtained from Pitt the Treasury grant by which the Board was established, and after 1808 he was incapacitated by blindness and old age. The Board produced one valuable piece of work in the "Statistical Surveys" of the counties of England, and it did good service when, as above mentioned, it appointed Davy its professor. It followed the example of the Society by offering premiums, when the time for such offers had passed away, and beyond this it really did very little. It is probable that the fact of the Board's existence diminished the Society's interest in agriculture, and made its agricultural work less necessary.*

Soon after the Board was abolished, a very different institution for the promotion of agricultural science came into being, for the Royal Agricultural Society was founded in 1838. From its first start it secured the support of all interested in the subject, and was at once recognised as the fit representative of British agriculture. From that date there was nothing more for the Society of Arts to do. But until the interests of this great industry passed into its competent hands it can be truly said that they were well looked after by the older Society. Amongst all its multifarious objects there were none more zealously pursued than those associated with agriculture. "Nor," in the words of the writer of the above-quoted preface—probably Arthur Aikin—"is it unjust to suppose that the unexampled rapidity with which the art of cultivation has advanced to its present state is in no small degree owing to the protection originally conferred by this institution."

THE NATIONAL LABOUR EXCHANGES.†

By Robert A-Ababrelton, F.R.G.S., F.S.S.

The Labour Exchanges under the control of the Board of Trade are authorised by the "Labour Exchanges Act, 1909." These Government Exchanges commenced on February 1st, 1910. On that day some fifty-eight Exchanges were opened. During that month the number rapidly increased, about ninety being at work by the first day of the following month. Since then others have been added, so that some 230 are open in Britain at the present time; and it is officially anticipated that there will probably be 300 in operation by the end of this year.

The old Labour Bureaux, or Employment Agencies—started with the best intentions by Distress Committees in their endeavour to find occupation for the unemployed, who were clamorously insisting that work of some kind

* An account of the Board of Agriculture, by Sir Ernest Clarke, will be found in the *Journal of the Royal Agricultural Society*, Vol. IX. (Third Series, 1898) p. 8.

† Paper read at the Economic Section of the British Association, Portsmouth, September 1st, 1911.

must be found for them—whilst directing public attention to the necessity for properly organised National Labour Exchanges, were also the cause of a general idea that only casual or unskilled labour would be registered therein, and consequently that skilled workmen would be unable to secure employment through the Government Exchanges.

At first considerable difficulty was experienced thereby, both in persuading employers to notify vacancies for skilled labour, and also in persuading skilled workmen to apply for employment at the Exchanges. Fortunately these difficulties have been rapidly overcome on both sides. Skilled workers are now applying in larger numbers each week. During May of this year, out of a total of 7,052 vacancies filled in the building trade, only 1,004 (just over 14 per cent.) were by unskilled men, the remainder being skilled workmen. In the engineering and machine-making trades, the proportion was 9·7 per cent. labourers, and 90·3 per cent. other workmen.

It was also necessary, at the very beginning, to grapple with the dislike of the workmen to have anything to do with an organisation which might be supposed somewhat to favour the employers, and at the same time to make employers understand that the Labour Exchanges had no bias in favour of the workmen, but were absolutely fair to both parties. Advisory trade committees were set up in connection with the Labour Exchanges, the membership thereon being equally divided between employers and workmen, so that each side is properly represented. Instead of the Board of Trade appointing the members entirely of its own motion, the trades organisations are consulted, and asked to nominate those who are to represent them on these committees.

It will probably be remembered that very soon after last year's session of the British Association in Sheffield, the Trade Union Congress was held in that city, and some strong remarks were made by certain leaders against the Labour Exchanges established by the Government. The principal complaints were that the Labour Exchanges were becoming agencies for procuring underpaid labour, and that, by favouring employers, they were undermining Trade Unionism. These matters were satisfactorily answered shortly afterwards, when the complaints were formally laid before the Board of Trade, and experience gained since has proved such complaints to be unfounded. The Labour Exchanges do not interfere between workmen and employers in the matter of wages or anything else. They do not manufacture vacancies, start relief works, or dispense charity in cases of distress. They merely act as intermediaries between workpeople seeking employment and employers wanting workers. There is, however, one class of labour which is excluded from the operations of the Labour Exchanges, namely, indoor domestic servants. Until the present instructions are altered, the servants' registry, with its fees, is the only registration office open to domestic servants seeking employment.

There are no fees chargeable at any Government Labour Exchange against either employer or employed. The employer is invited to notify the nearest Exchange of any vacancies in his establishment (except, of course, for indoor domestic servants), and he can do so by means of a postcard supplied to him, which is officially stamped. If he sends a postcard or letter, or messenger, or communicates by telephone or otherwise, the Exchange duly registers his requirements directly they are received. As soon as possible, from amongst the applicants registered, the Exchange will send him those men who appear to be the best qualified to perform the work required. If so desired, the employer or his foreman can interview the men at the Exchange itself. If workpeople of the kind needed are not registered locally, they can probably be obtained from another locality. The Exchanges are continually in communication with each other and with the central offices for that purpose. Suitable applicants may also be specially notified. I am distincly informed by managers and other Labour Exchange authorities, that the only qualification taken into consideration in submitting applicants to an employer is the industrial suitability of the workmen for the work offered, and that no regard is paid by the Exchange to other considerations, not even as to how long the applicant has been registered.

The employer retains his entire freedom of selection. He is even at liberty to let the Exchange know of any particular man whom he wishes to interview, and if that man is available he will be notified accordingly. The employer is expected to inform the Exchange of any persons engaged by him through its agency. Employers are now becoming so satisfied with the working of the Exchanges that they are making it a rule only to engage men through the Exchanges. Nearly five thousand enamelled plates giving this notice have already been issued and affixed to warehouse gates, etc.

I have visited Exchanges *incognito*, and have found that the applicant for employment need not fear, by going to a Labour Exchange, that he will be made to feel he is under any obligation to the authorities. He is not thereby seeking relief, or proclaiming himself to be an individual in distress. If he has had any experience of the ways of the officials of Distress Committees, he will be agreeably surprised. He will now find himself treated by the official at the counter more like a friend or comrade. All necessary questions are put to him quietly and sympathetically. He is not sharply questioned as to his past life or his domestic affairs; he is not asked to disclose any private matters; the object of the inquirer is merely to discover, as far as he possibly can, for what work the applicant is most suitable, and whether he will be likely to fulfil the requirements of certain vacant posts. From long practice, the officials are very apt at gathering what will probably be most suitable for the applicant under present-day conditions. It may be that he has fallen out of work because

he belongs to what may be termed a "dying" trade, such as coach-building, and that there is a growing industry, such as motor-car building, into which he could be introduced. There is no hesitation in offering similar advice to suitable men. If any questions are asked which it is inconvenient for the applicant to answer, he need not reply to them; but he is told that the fuller the information given, the greater the chance of suitable employment being found for him. The particulars obtained are entered on a "B" registration card, which is only filled up by the Exchange officials, and is treated according to the card-index system, the occupations of the applicants being elaborately subdivided for purposes of easy and rapid reference. If there are any suitable vacancies on the list, the applicant is at once informed of them, and he can be sent off immediately to the employer with a green identification card duly filled up by the official, who encloses it in a sealed green envelope addressed to the employer.

If the bearer of the identification card is engaged by the employer, the latter simply signs the card as "engaged," and drops it into the post. It is already stamped officially, and addressed to the manager of the Exchange from which it emanated. Until the card is received from the employer, or other information obtained disposing of the matter, the situation is considered open. If the employer does not engage the bearer, his identification card is handed back to him, and the applicant is expected to notify the result to the Exchange as quickly as possible. This he may do, either by calling there, or by posting the card. As it is not signed by the employer as "engaged," the officials know that for some reason the applicant has not been chosen.

To save time and trouble to himself each applicant is asked to register at the Exchange nearest to his home. As this is largely a matter for his own convenience, considerable latitude is allowed. For instance, persons usually employed in the City of London may register at the City Exchange instead of near their own homes, if they wish. This simple "registration" of an applicant lasts only a week, thus keeping the applicant in touch with the Exchange for "re-registration," if he has not been "placed" before that period has expired. He is generally asked to present himself at the Exchange once a week whilst disengaged. He may, however, call there as often as he pleases, within reasonable limits. The officials are generally able to tell him the best times to look in for information as to suitable vacancies. These are also notified in the windows of the Exchange.

The employer and the workman are quite free to make their own bargain, and no workman is prejudiced as regards his chance of future employment because he has refused a vacancy owing to some trade dispute, or because the wages offered were insufficient. If a strike or dispute is known to exist, the applicant is informed thereof, and is left at liberty to apply for the vacancy or not, as he may think proper. Directly an applicant obtains employment, either through his own efforts or by means of the Exchange, he should fill up his own registration card, which is officially stamped, and post it, so that it may be known he is no longer seeking employment.

Should there be work awaiting an applicant at a considerable distance, the Exchange will take the matter in hand, and, if an engagement results, will advance travelling expenses if circumstances require it. This is generally effected by means of a railway warrant. The mode of repayment is arranged between the parties concerned. During the first thirteen months of the existence of these Exchanges, a total sum of about £2,400 was advanced in this way in nearly 9,000 cases altogether. During that period £2,200 had been repaid.

To keep the statistics clear, if the applicant is not "placed" within a week, his "registration" expires; but he can "re-register" for as many other weeks as may be required. It should also be mentioned that sometimes an applicant who has been "placed" falls out of employment through temporary job, slackness of trade, or other cause. He may then be re-registered as "Re-registered after placing."

Sometimes an applicant prefers not to answer verbal questions when registering himself. In that case, he is given a form to fill up which is headed, "Answers to these questions are not compulsory, but it will be easier to send applicants to suitable employment if they fill in the form as completely as possible." The questions asked upon the form are name of applicant, address, age, work desired, last employer and previous employer, qualifications, when free, etc. From this form the official fills up the "B" registration card which is kept in the Exchange. These forms are also useful when many applicants are needing attention at the same time. Instead of keeping them all waiting they are asked to fill up these forms, which can then be dealt with expeditiously.

The opposition of the Trade Unions to the Labour Exchanges seems to be disappearing. Trade Union branches are now beginning to hold their meetings in rooms at the Exchanges, rather than in public-houses or other unsuitable places.

At each Exchange there is a separate department for women, with a female staff. Men and women enter by different doors, and are interviewed in entirely distinct rooms. To avoid mistake, it is perhaps necessary here to reiterate the fact that ordinary indoor domestic servants, female as well as male, are not allowed to make use of these Exchanges.

In general, there is also a separation between the skilled and unskilled of both sexes, and there is also a juvenile department for boys and girls below the age of seventeen. This juvenile department is subject to the rules made by the Board of Trade after consultation with the Board of Education so far as regards England and Wales, with the Scottish Education Department so far as regards Scotland, and with the Lord Lieutenant

of Ireland so far as regards Ireland. Juveniles applying for employment are registered, and special advisory committees are formed for the purpose of giving information, advice, and assistance to boys and girls, and to their parents, with respect to choice of employment and other cognate matters.

This system of Labour Exchanges has now become national. It is divided into ten territorial divisions, each with a central office or clearing house. These central offices are controlled by, and are in direct communication with, the chief central office in London. There must always be a certain amount of unemployment, even under good conditions. A workman finishes a job and is on the look-out for another. Until he finds it, he is one of the unemployed. The great aim of the Labour Exchange is to minimise that period of unemployment, and to abolish unnecessary tramping about in search of work. Mr. Beveridge, who is now the Director of these Labour Exchanges, in his valuable work on "Unemployment," states during the good year 1890 the proportion unemployed in the engineering trades at some time during the year was 21·4 per cent., whilst in the bad year 1893, the percentage only rose to 26·4. It will be interesting to note the percentages in good years and bad years when these Exchanges are in full operation. They are now filling over 10,000 vacancies each week. These are mostly for skilled labour.

Those who direct the operations of the Labour Exchanges are to be congratulated on the great adaptability to circumstances displayed in their working. The different entrances for men and women, and for employers and employed, the separate staffs for the different departments, and the separation of the skilled and unskilled, are instances in point. The Exchanges are generally open from Monday to Friday, from eight in the morning till five in the afternoon. On Saturdays they close earlier. But where a change is necessary, it is speedily made. One Exchange opens in the morning at four o'clock for the convenience of workmen. In the textile area in Manchester some Exchanges are open at six o'clock. All these early openings are conducted by a relay of staff.

Now that the value of these Exchanges is being realised, the number of employers notifying vacancies is continually rising, and a large measure of support is increasingly given by other Government Departments. In course of time, one may anticipate that only the "ne'er-do-wells," the "undesirables," and those who are called "wasters" in the British oversea dominions, will shun these Exchanges. Then every respectable workman or workwoman seeking employment would apply there as a matter of course, and every employer in want of workpeople would there make known his requirements. The great prejudice throughout the Dominions oversea against anything which can be called "interference" on the part of the Motherland, is well known. So is the Colonial fear that the Colonies may be made the dumping-ground for "undesirables" from this country, if the Labour Exchanges are permitted to extend their operations Oversea.

In these days of advanced ideas, surely one may be permitted to look forward confidently to a time when this prejudice, like other prejudices against the Exchanges, shall have faded away, and each portion of the British dominions will be doing its proper part in enabling a Grand Central Clearing House for Labour to overcome the evil of unemployment throughout the British Sovereignty, by a still greater national scheme working on the present lines of strict impartiality between employers and employed.

To afford some idea of the ordinary work of the Labour Exchanges, a table is printed giving the number of applications received, vacancies notified, and vacancies filled during certain periods. The percentage of vacancies filled rose from 59 per cent. on the first month's working to 81 per cent. on the average during 1910. It still varies, but appears to be keeping between 80 and 90 per cent. on the ordinary register at the present time.

The cost of the Labour Exchanges was recently stated in Parliament to be about £250,000 per annum. At present a considerable sum has to be found for initial expenditure, which will not recur. Some time must elapse before it will be possible to give a trustworthy estimate of the annual cost to the nation for this service.

Being in a position to obtain early and accurate information on the spot in cases of labour troubles, the usefulness of the Labour Exchanges is thereby largely increased. This latter work is done unobtrusively but effectively.

Owing to limitation of time it has been impossible to do more than mention several points which deserve fuller consideration.

THE PRODUCTION OF VEGETABLE IVORY IN ECUADOR.

An important industry in Ecuador lies in the export of vegetable ivory. The Spanish name is "coroza," but another similar nut is sometimes confused under the same designation. The fruit of the tagua palm furnishes this article of commerce, which has proved to be an excellent substitute for the elephant tusk product, and has been found useful in other ways. The tree grows wild along the west coast of South America, from Panama, through Colombia, Ecuador, and Peru. It is a stunted palm fern, growing from ten to twenty feet high, with a very short trunk, which is crowned with fronds of large bright green feathery leaves. In blossom the flowers give off a strong perfume, and the fruit is somewhat similar to the cocoanut, growing from four to nine to the tree. The fruit weighs nearly twenty pounds, grows to about the size of a man's head, and consists of a woody, fibrous, wart-covered wall, that encloses the seeds proper, which are of hard white composition, small potato sized, fine grained, and approaching real ivory in its characteristics. The head holds from six to nine seeds. According to a recent

report of the Pan-American Union, the seed, when very young, contains a clear insipid fluid, which serves the thirsty jungle traveller as water; but, like the cocoanut, this liquid quickly becomes milky and sweet flavoured, and then the small native animals find it most appetising. As climate affects the development of the tree, so a considerable variation will be found in the form and composition of the tagua nuts that grow under conditions of excessive rainfall, and those gathered in the dryer climates. As the plant grows wild and uncultivated, the time of bearing is not accurately known, but it is judged to be about the sixth year, and the life of the tree is estimated at from fifty to one hundred years. Natives gather the fruit of the tree, taking those nuts found on the ground which are matured. Immature seeds have a soft spot in the centre, which makes them less valuable, so care must be exercised in selection to avoid faulty fruit. The vegetable ivory is sold to a local merchant or exporter. The market price is governed by the competition of these exporters, which is resultant upon the European and American market. Some German firms keep quantities of the nuts stored, to be sold only when the market is most favourable. The principal use of vegetable ivory is the manufacture of buttons. Some vegetable ivory is used in making umbrella handles, chessmen, card counters, and similar articles that are also made from the dentine ivory, but the largest proportion by far of the vegetable product is bought up, to be turned into buttons. Turning out ivory buttons is an industry that gives employment to many persons in Europe and the United States. The process of changing the dried tagua seed into fancy waistcoat buttons is varied, complicated, and is carried on in extensive plants fitted with many different kinds of special machinery. The average annual export of vegetable ivory from Ecuador is 20,000 tons. Colombia has a fair share of the trade, with yearly increasing exports from Cartagena and Savanilla. Although in recent years a limited amount of this product has been sent out of Africa, yet the real home of the tagua palm is Central and South America, where it is a considerable source of wealth to the countries producing it.

ITALIAN TOMATO PRODUCTS.

The province of Naples has for years been noted for the production of a species of tomato specially suited for the manufacture of tomato sauce, extract, and paste. The fruit is small, thin skinned, free of fibre, and has small seeds, and a special flavour that is greatly relished by the Italians when prepared as a sauce to be eaten with macaroni and other farinaceous products. In the manufacture of tomato sauce and paste the fruit used in the preparation is fully ripe, the unripe fruit being set aside in baskets to ripen before being used. Speckled or mouldy fruit is placed in a special oven, dried, and afterwards made into an inferior class of thick tomato paste, which is not exported. The United States Consul at Naples says that it is the custom to prepare the fruit within a day after it is gathered. It is first carefully sorted, and then washed in hot water. Afterwards it is sorted again and washed in cold water, then automatically carried to the tables to be peeled. The residual parts of the fruit, such as skins, are automatically dried, in some cases to obtain cellulose. Oil is extracted from the seeds. Often the peels are sold for food for cattle or for fertilisers. The waste materials are said not to enter into the composition of the product. In the process of manufacture the fruit is pulped by air blasts as needed, and is then run into automatic boxes with double bottoms, the lower compartment of which is filled with steam, which maintains the product at a temperature of about 176° F. The concentration is effected previously by means of a vacuum. After being cooked it is canned immediately in tins which have first been submitted to sterilisation, by means of steam at 194° F. for thirty minutes. Then the tins are closed and sterilised again for another twenty minutes at a temperature of 230° F. Whether fermentation is desirable in the preparation of these products appears to be a matter of opinion among the manufacturers. One proprietor has stated that he endeavoured to prevent fermentation, as it affects the tins, and a large exporter stated that fermentation is sought in the preparation of these products. In one method, fermentation is brought about by a slow process of heating. Another provokes it by the use of selected germs. After the fermentation is produced, it is checked by the addition of salt in small quantities. Each time the work is suspended all vessels that have come into contact with the fruit at any stage of the manufacture are washed with a solution of bisulphide of soda, with boiling water, and finally with cold water.

THE CANE INDUSTRY OF THE SOUTH CHINA COAST.

There is a considerable trade carried on between the South China coast and Europe, and the United States, in fancy cane materials, and there is some confusion as to the exact nomenclature of these materials. For example, what is known in Europe as a "Tonkin stick" is unknown in Hong-Kong by that name, while among some manufacturers of Europe and the United States, what are known in China as "Annamite sticks," are taken to be what are known in China as quite another cane. In general, the trade is divided into two lines—those known in China as simply "canes," or sometimes as "Tsinglee canes," and generally identified with the name "Tonkin stick," and the "Annamite sticks," also known as "Partridge canes." The former are the well-known bamboos of the finer fishing-rod trade, which also are used for canes, umbrella handles, etc. The latter material is that peculiarly coloured cane with short sections, which has grains of dark colours running lengthwise, a bulbous root, usually used as a handle, and is a heavy wood

susceptible of a high polish. According to the American Consul-General at Hong-Kong, the name of "partridge stick," or "partridge cane," arises from the beautiful variegated colour of the cane. The name "Annamite stick" comes from the country or district in which the canes were first produced for the market. Most of this variety of material comes from Saigon and Indo-China generally at the present time. A considerable portion of the Tsinglee cane, or Tonkin stick, also comes from Indo-China, but at present the greater part is grown for the market in the delta lands of the Pearl River between Hong-Kong and Canton. It is difficult to generalise as to any portion of this trade, as prices and sales depend so largely upon special qualities that price quotations are always somewhat uncertain, the particular use for which the canes are required also determining the nature and quality of the stock. Of late, there has been an increasing demand for the "partridge canes," or "Annamite sticks." These are a variety of cane or bamboo which grows with a peculiarly swelled bulbous-like root, with few, if any, smaller roots projecting from it. The cane is pulled, not cut. When first pulled these small roots are removed, leaving the swelled end smooth, and when properly dried the root takes a high polish and forms the handle of the cane or umbrella stick. These canes have a dark brown colour generally, the colour running largely in lines up and down the cane. For some purposes this colour is the prime requisite of the stick. To have it regular and attractive the cane must be dried evenly, and must, of course, be free from imperfections due to disease or injury. The real colour of the cane does not readily appear upon its surface, and to ascertain or test it the buyer of the cane scratches the surface in a number of places, after it has attained some degree of dryness. The deeper the colour is found to be under the hard surface, the more valuable it is. The value of a stick is determined by its diameter, its colour, the quantity of root, its length, and its degree of dryness. At the present time about 4,000,000 "partridge canes" and 25,000,000 "Tsinglee" or "Tonkin canes" are exported from Hong-Kong annually.

THE JERKED BEEF INDUSTRY OF URUGUAY.

Some idea of the magnitude of the jerked beef industry may be gained when it is known that in Uruguay alone there are twenty-three establishments called "saladeros," where the preparation is carried on, while in the river region of Argentina and Brazil they number twenty-two, giving employment to thousands of men. It is stated that the persons employed in this industry are unable to eat meat of any kind during the killing season, owing to the constant odour of fresh blood about them. The number of cattle killed at the saladeros of the River Plate region, consisting of Uruguay, Southern Brazil and Argentina, in 1908, was 740,800; in 1909, 1,062,800; in 1910, 1,233,208; and in 1911 up to May, 1,024,400. In the establishment of saladeros where the cattle are slaughtered, and the beef cured, a piece of land several acres in extent is selected, on which are erected the buildings needed for this industry. The principal structure is usually about 175 feet by 100 feet, and 40 feet high, with a brick foundation, the sides of brick, pine, or galvanised iron, more or less open and covered with a corrugated iron roof. In an enclosure at one end the cattle are killed by driving a knife-blade into the spinal cord just behind the base of the skull. The animal is then carried into the building and dropped on the cement floor, where the hide is dexterously removed and the carcase elevated to a travelling tackle running on a trolley cable. The United States Consul at Montevideo says that the usual method is followed of removing the waste and quartering, the bones being removed so skilfully that the flesh, after a few slashings, forms a large, flat, single piece, which is allowed to hang for a few hours for the animal heat to pass out. It is then thrown into a large vat in the floor containing a very strong brine, where it remains for several hours, to be afterwards piled between layers of salt. After a varying period of time the meat is removed to the open air, where it is again stacked and salted, the drying process continuing there for several months. Acres are covered with these piles of meat to a height of ten feet, salt frequently being thrown over the surface. If rainy weather appears the meat is covered with a strong tarpaulin, although windy, cloudy weather is preferred to sunshine. When ready for the market "tassajo" is black in colour, a few feet square, and an inch or two in thickness, and as hard as sole leather. Very little tasssajo is eaten in Uruguay, the greater portion being exported to Brazil, Cuba and Porto Rico, where it is eaten raw, or boiled for some hours, and is preferred to a choice steak. Near the principal building is a smaller one, used for curing and storing hides. The floor is of cement, into which are sunk several large tanks half-filled with brine in which a certain quantity of corrosive chloride of mercury has been dissolved. After removal from the animals, the hides are thrown into the vats, remaining thirty hours, and are then spread out on the floor, one above another, and well salted. After curing for some days, the hides are baled ready for export. Another building in close proximity contains the boiling-room, where the fat is extracted from the bones, head and intestines, to be made into soap and candles.

HOME INDUSTRIES.

Railway Workers and the Public.—It is not very surprising that the report of the Railway Commissioners has given satisfaction to neither side. At present the companies are silent, but the representatives of the men are discontented, and there are renewed threats of a strike. Meantime the Great Western Railway Company is considering a scheme to improve the wages of their men belonging

to the lower grades, and there is pretty general agreement that the position of porters, carmen, shunters, checkers, and the variety of other occupations engaged in handling and forwarding goods must be improved. The problem is how to do it. Where is the money to come from? All the railway companies are not in the happy position of the Great Western. Nor is it likely that the public would readily consent to reduction of workmen's trains, week-end tickets, and excursion facilities. It was suggested before the Railway Strike Commission sat that if the companies found that their recommendations were to cost them much they should have the right to call upon the Government to sanction increased rates. But the Government may well hesitate before they assent to that demand, for it would mean an agitation on the part of the railway users of a very formidable kind. The complaint of the trading classes is that as matters stand they are seriously handicapped in competition with trade rivals abroad by the high railway rates they have to pay, and if these rates were increased it would be a very serious matter. It is not easy to see a way out of the difficulty, for three things are certain: (1) that large numbers of the railway workers are much underpaid, (2) that the present return upon capital invested in railways is less than it ought to be, and (3) that traders cannot afford to pay higher railway rates.

The Tobacco Trust.—The figures relating to the number of licensed tobacco manufacturers continue to decrease. Year by year since 1900 they have lessened. In that year they numbered 502, in 1910 they had fallen to 383, the official estimate for 1911 is from 340 to 345. The British tobacco manufacturing trade is divided into two parts—the staple trade, comprising fully one half (roll, twist, and shag retailing at 3½*d.* per oz.), and a proprietary trade, which is as profitable as the staple trade is the reverse. This proprietary trade consists of package cigarettes and packet fancy tobaccos, retailing at various prices quite out of keeping with their intrinsic values. So profitable is this proprietary trade that when the duty was increased by eightpence per pound it was not added to the retail price of certain well-known proprietary brands, the reason for this being that the articles in question were profit-bearing over and above eightpence per pound. On the other hand profits on the raw material are said rarely to go much beyond a halfpenny per pound, nor is it possible for it to rise very much in price. It is suggested that the salvation of the independent manufacturers would be found in reducing the duty to the point which will permit the sale to the workingman of an ounce of tobacco for twopence-halfpenny (it now pays duty relatively to the amount of about ninepence as against fourpence-halfpenny in the shilling spent by the richer consumer), and in supplementing it by an *ad valorem* stamp duty on cigarettes, cigars and tobacco, loose and in packages, based on their retail price to the consumer.

The Sugar Industry.—The statistical position of sugar does not suggest the likelihood of any early or considerable fall in prices. At the time of writing the price of 88 beet sugar is over 17*s.* per cwt., as against 8*s.* 6*d.* a year ago. This doubling of the price is due to a diminution in the visible stocks, and the certainty of serious shortage in the coming crop. It is believed that the total yield this year will be about 2,000,000 tons short as compared with the actual harvest of the previous season, 8,095,000 tons. The European production of sugar in the current season will not be more than three-fourths of that of last season, and the normal consumption of the world steadily increases. And there is the serious diminution in the visible stocks and floating cargoes in Europe and America, which in the middle of the present month amounted to 665,957 tons as against 831,622 tons at the same date last year. As to cane sugar, the crops are not expected to be materially different from those of last year, with the exception of Cuba, where it is expected that the crop will exceed that of last year by at least 500,000 tons. The position is complicated by uncertainty as to the Russian bounty. Russia is the one country in Europe where the beet crop this year is largely in excess of that of last year. Russia has a surplus of half a million tons from her 1910 crop, and her present crop is so large that it is possible that, with the surplus on hand, she may have at least a million tons more than she can consume or dispose of in her regular trade with the non-Convention countries in the East. Now this, with the half million extra tons from Cuba would go far to put things straight. But here the Convention has to be reckoned with, which prevents Russia, without the express permission of the Convention countries, from exporting to them more than 200,000 tons in any one year. Russia has applied for permission to increase her exports. Will the Convention countries grant it? It is very doubtful whether Germany and France will consent.

Mill-Driving.—The Textile Mill-Driving Joint Committee has decided to conduct an investigation into the various forms of mill-driving, and the first step in the investigation will be the collection of statistical information about the various kinds of motive power used in the United Kingdom, the United States, Canada, and most of the countries on the Continent. After obtaining this information the committee will decide the future course of the investigation, which is intended to cover (1) the relative merits of the different motive powers; (2) the relative merits of the different methods adopted in electrical driving; and (3) the relative cost of power in relation to the output of material for different motive powers employed. The whole object of the investigation is to give the trade an authoritative report, not only on the relative merits of motive powers, but on the relative merits of distributing power. For the purpose of collecting preliminary statistics the Textile Institute has been divided into five sections,

and a separate sub-committee has been appointed for each. The sections are cotton, worsteds and woollens, linen, silks, and hemp and jute. A special sub-committee has also been formed to conduct the investigations outside the United Kingdom, to deal with all sections of the textile industry. The opinion is gaining ground that electrical driving is making greater progress abroad than in the United Kingdom. It is expected that the investigation will be of an exhaustive character, and that it will last for more than a year.

Automatic Sprinklers.—The use of automatic sprinklers in warehouses has increased considerably of late years, and the insurance companies grant discounts where these machines are used, amounting in some cases to as much as 80 per cent. of the premiums. These sprinklers have frequently demonstrated their value on the occasion of fires, and it is suggested that they would be more effective still if the practice of suspending large numbers of healds close under the sprinklers was abandoned. In most buildings it would not be a very difficult matter to arrange for the healds to be lowered so as to allow the sprinklers room to distribute water effectively. Another suggestion is that separate buildings should be provided for the storage of healds, but in premises let to a number of tenants there are obstacles in the way. Moreover, the insurance companies do not make any allowance for this separate storage, which seems a little surprising when the inflammable nature of healds is remembered.

The Pit-Brow Women.—It is natural that Mr. Smillie's statement at the Conference of the Miners' Federation is attracting attention. As president of the conference Mr. Smillie defended the resolution to forbid women working at the pit brow, and said: "They were not ashamed for wishing to keep women off the pit bank, from the laborious, unhealthy employment, in order that many of their elderly men might find employment when they were no longer able to do full work underground." The obvious retort of the suffragist is that the real reason why workingmen object to women working at the pit brow is that they want the work for men. The case for the women is put very well by Miss Alice Kemp, who says: "These women have to live, and are among the five million wage-earning women in this country. Often the men who talk so glibly of the 'home as the woman's sphere' are precisely those who entice her out of that same 'sphere' by offering her equal work with man at half his pay. With regard to this 'laborious, unhealthy employment,' it has been stated that many of the women (at Wigan) have left the mill on account of ill-health and taken up work on the pit brow, and have greatly benefited by the change. This is not to be wondered at. From the crowded, stifling room, with closed windows and intense artificial heating, their life is now passed in the open air, and has a certain amount of movement in it." Miss Kemp goes on to say that some time ago Miss King-May, an expert in physical culture and a trained masseuse, gave up her Easter holiday of a fortnight in order that she might test the healthiness of this occupation for women. She herself worked at the pit brow, and came to the conclusion that the strain upon the women was by no means too heavy, and that the outdoor life gave vigour and robustness.

CORRESPONDENCE.

THE AMETHYST, ITS VIRTUES, AND ITS NAME.

I am moved to contribute an illustrative comment on certain statements as to the etymology of the word "Amethyst," and the imputed mystical properties of the stone [both the silicious, and the aluminious], made by Mr. Alfred E. H. Tutton, in his Lecture on "Rock Crystal," coll. 1 and 2, page 1092, published in yesterday's issue of the *Journal of the Royal Society of Arts.*

The Amethyst is the *al martas* of the Arabs, the Tamil *sugandi*, and Cyngalese *skuandi;* these three Oriental names, each everywhere in India including two totally different stones, the silicious, or occidental Amethyst, and the aluminious, or "Oriental Amethyst," so phrased by European jewelers, a true corundum [Tamil *kurundam*], differing only in colour from the sapphire and the ruby, and so hard that, even in India, it is often, when decolorised, palmed off as a veritable diamond. Like all the "rock crystals," and all the true gems, or "precious stones," it has been used from the earliest antiquity throughout the East, as an amulet, talisman, phylactery, prophylactery, charm, etc. Its earliest mention, known to Europe, is in Exodus xxviii. 19, under the name of *achlamah;* and after that by Theophrastus, "Stones," xxxi., who is the first to name the stone "the Amethyst" —ἀμέθυσον; the name we find in "The Revelation of St. John the Divine," xxi. 20, in the form of ἀμέθυστος. Theophrastus, "Stones," xxxi., and Pliny, "Natural History," xxxvii. 9 (40), and ix. 65 (39), are the only two classical writers of authority on its alleged virtues in the practice of sympathetic magic; while Plutarch, ii. 462, C. Dionysius Periegetes, 1122, etc., count for nothing in the controversy. Theophrastus says expressly that the stone is called "the Amethyst, [*i.e.*, 'anti(vinous)drunkenness'], because [on the magical principle of 'like cures likeness'] it is wine-coloured." Pliny gives the word the same derivation, but expressly ridicules as preposterous the pretence of the magicians who would persuade people that it is a preventive of surcharged potations. Yet there must have been something in the belief, for believers in it, or surely we should not so often find the Amethyst graven with Bacchanalian words, and symbols, and subjects, throughout the whole classical period of the glorious glyptic art of Greece and Rome, as in the Μέθη ring of "Great Cæsar's"

greater Cleopatra. If you wore such a ring, there would be a constraint against your filling up your wine cup to intoxication. There are many things in which, in this way, it is good to believe, although you know them to be false, materially. Pliny enumerates several sorts of Amethyst, including one of the rich purple tint "called by the people of India, *socon*, the stone itself being called *socodion*." This is the "Oriental Amethyst" of our world; and with the instances before me of *corundum* being so named from the Tamil *kurundum*, and the Balas Ruby, from the Hindustani *Lal-i-Badakshan* ["The Red (stone) of Badakshan," on the Oxus], and Lapis-Lazuli from the Lajwardi mines of Persia, and Turquoise from Turkey, there can be no doubt of Pliny's *socon* being the Cyngalese *skuandi*, and his *socodion* the Tamil *sugandi*. And, to rush in where more responsible etymologists might fear to tread, I will adventure the suspicion, indeed, the suggestion, that the Arabic word *al martas*, which I find written also *al martees*, is none other but the very word "Amethyst" itself, modified in its passage through Egypt and Syria into Greece, where it was perfected to its final European form, in order to give it the full meaning in Greek suggested by the immemorial reputation of the stone as "a means of grace" in the pursuit of one of the most imperative of Pythagorean temperances.

Going back from what Pliny writes, xxxvii., of the Amethyst stone, to what he says, ix. 65 (37), about the pushful dyers of Rome, always on the rack, by mixing colours, in hope of blundering on some novelty of tint, hue, shade, or tone as a good advertisement ["nomen improbum"] of their skill, it is evident that the Amethyst dye he there describes [cf. Martial I. xcvii. 7] was also of the depth and lustre of the purple "Oriental Amethyst," and not of the washed-out purple of the European Amethyst; or of "fluor spar," our British "Blue-John."

GEORGE BIRDWOOD.

October 28th. 1911.

IMPERIAL COLONIAL DEVELOPMENT.

In continuation of the correspondence on this subject in the *Journal* of August 18th last, Mr. Enock's scheme of imperial colonial development, viz., the endowment of British municipalities with areas of colonial lands, appears to have been evolved from a conviction that, firstly, there is not as great a demand for artisans in the British overseas dominions as there should be; and, secondly, that Britain has an overplus of artisans for whom she has little or no use. If Mr. Enock's policy will remedy these defects, then I am heart and soul with him in the scheme.

Mr. Enock complains that the colonies are draining the old land of her best agricultural workers, and he likewise complains that they do not sufficiently encourage town workers. The reason for this is not far to seek. Australia has vast tracts of arable land. There is always a ready market in the world for the products of the soil. What is more natural than the anxiety of those responsible for the well-being of Australia to see this land under cultivation? To bring about this desire, Britain is called on for her yeomen.

As the land is settled the demand for artisans increases, and those who can afford to leave England do so. Every man who emigrates usually leaves a job to do so, and a vacancy is thus created for one of the poorer class to fill. Does Mr. Enock propose that the British municipalities should change the order of things—send the artisans first to build the houses and manufacture the machinery for potential settlers?

The course followed in settlement, at present, is something like this. Let us assume that the Land Department in Victoria have 100,000 acres of suitable land available. It is balloted for in 1,000 acre blocks, 100 farms. Of the 100 successful applicants, say, fifty are farm hands who have been working for wages for about five years, and having saved a little money desire to have a farm of their own. Thus fifty vacancies for farm labourers are created. To fill these vacancies Britain is drawn on. Does Mr. Enock propose under his scheme to put fifty artisans into the jobs?

To continue. The successful settlers desire to engage help for their farms. They intend doing most of the work themselves, but there are lots of little jobs that a youth or town labourer could do. Such settlers usually apply to the British Immigration League or the Immigration League of Australasia, both of which are doing good work in sending out lads from the home cities to Australian farms. No Government could do more than this without placing their country hopelessly in debt and incidentally penalising the settlers for whose benefit the money had been spent.

The British municipalities could only create a temporary demand for artisans, and the artisans thus would eventually be in as hopeless a position as if they had remained at home.

The demand for town workers can only keep pace with—it can never outstrip—land settlement in an agricultural country. To attempt to reverse this order of things is bad Imperialism, not to say a hopeless task. Imperial colonial development must be conducted on business lines.

The interest that Mr. Enock takes in this very important matter shows that he is a good Imperialist.

If from the ashes of our discussion there rises one practical idea to improve the condition of Britain's workers, and bring about a better understanding between the old land and her sons across the sea, I shall feel that not in vain have I suffered the bites of the famous Gold Coast sand-flies while penning this.

A. G. REID.

Obuasi, Gold Coast Colony.
October 5th, 1911.

Mr. Enock, to whom the foregoing letter has been submitted, writes as follows:—

It would seem from Mr. Reid's letter that he has not read my paper, given before the Society

where his objections are answered; or, if he has, he cannot, or will not, grasp the plan advocated. I have also gone fully into the subject in my book, "An Imperial Commonwealth," published last year.* The purpose is not to supply colonial farmers or manufacturers with labour—that will take care of itself—but to bring about an intensive system of "re-colonisation," making use of uninhabited colonial lands and surplus labour at home. Mr. Reid, like many others, falls at once into the error of supposing that it is intended to dump town labour into the colonies, unprovided for, and put it to work at the plough.

The purpose is to establish new communities which, as far as possible, would be self-supporting, and which would ask nothing from colonial governments beyond the land—either as a free grant or in purchase. Upon these new areas industries would be developed, both agricultural and industrial ones depending upon agriculture. In this no excess of artisan labour would be permitted. The only rational way of meeting the grave conditions in Britain, of surplus artisan labour (conditions not unknown in the colonies), will be by a system of "re-colonisation," as I venture to term it, where due regard is had to the proportion of land workers to hand workers. This, of course, is to some extent the "garden city" idea, but it will have to be carried into a broad "industry-planning" scheme.

Very well, the time is coming when this will be done at home; when it will be recognised that every human unit, under organisation, is of producing and national value. When that comes about there will be much less emigration, and the tendency of governmental legislation in England lies that way—in giving a freer access to the land. But what I want to do is to anticipate that time, creating new centres of industry overseas for our overcrowded people at home. Mere emigration alone will not accomplish it. The British ratepayer, like all others, expects to get something for his money. He is not prepared to assist in any scheme of emigration which gives no return for capital invested, and this is reflected in the attitude of the Government, which will not, so far, sanction any plan of State-aided emigration.

The purpose I put forward is one of mutual self-help and profit, under which every British municipality, city, or shire, would establish its own colony, of course under the colonial *régime*, and gradually merging into the colonial communities, except that the "property" continues to return an interest on the money and effort which established it from home.

It is at least strange that the self-governing dominions have not yet put into practice some analogous plan or organisation. Instead of this, they come into the highways and byways of the old country and take away what we can least spare—our land-working people and domestic servants. We may not grudge them this method, but it is time to supplement it. They want population. Australia is nearly stationary; Canada has just been disappointed of a million in her census; but I do not believe that in the future they will continue to obtain it from Great Britain under the present haphazard system of emigration. Under organised, reciprocal methods, there is a large reservoir of people which could be tapped—people of less adventurous class than the ordinary emigrant, and people without funds for emigration.

But it is not much use arguing this matter on theoretical grounds. The fact remains that at home we have a great mass of human material in our towns which cannot live in sufficiency.

My social work in the poor quarters of London shows a state of things which can only be described as appalling, and if "Empire" is to be more than a mockery to this class, it is time for action and not words. The following fact may interest your correspondent and others, to whom this letter is a reply (for many have written me on the subject). It is this. One of the London borough councils advertised about a month ago for a "handy man," at 25*s*. per week. They got 750 replies!

The remedy for these matters lies in the hands of the people themselves on the lines advocated, but initiative is necessary. The selfishness and apathy which have to be overcome are as strong in the dominions as at home, but if they could be cast off, and the wheels of some unselfish organisation set in motion, then we could enter on a new and impregnable Imperialism. Let us recognise the commercial value of every able-bodied citizen, and every acre of colonial territory. If your correspondent—and others—will adopt this view, perhaps the "sand-flies" which are troubling him will disperse.

C. Reginald Enock, F.R.G.S.

* Grant Richards, Ltd., London, 1910. 3*s*. 6*d*.

CANADIAN COINAGE.

With reference to the paragraph on this subject in the *Journal* of October 27th (p. 1104), the Rev. William C. Piercy writes that the letters "D.G." were omitted by pure inadvertence from the new Canadian cents, and that fresh dies were sent out to Canada directly the mistake was discovered.

NOTES ON BOOKS.

The Soya Bean of Manchuria. By Norman Shaw. Shanghai: Statistical Department of the Inspectorate-General of Customs; London: P. S. King & Son. 3*s*. net.

The Statistical Department of the Chinese Customs has for many years been in the habit of issuing publications on commercial subjects, and of supplying its Agencies in Europe and the United States with copies for the use of those who were interested in the subjects treated; but in consequence of the sudden and remarkable growth in commercial importance of the soya bean of

Manchuria, the Department has been induced to publish in a more general way this monograph, which is the work of Mr. Norman Shaw, of the Chinese Customs Service.

Although the soya bean grows well in many parts of the world, the soil and climate of Manchuria seem to suit it better than any others. It grows in great varieties, yellow, green, brown, black and mottled. Photographs of these species are given, and further developments towards red, orange, white and blue seem to be possible. After describing these various kinds, Mr. Shaw discusses the methods of cultivation, soil infestation, and yield, and then follows an extremely interesting section on the uses of the bean. A number of these are, of course, very familiar. The bean has long been used in the East as soy sauce, from which the name soya is derived; as chiang, the common diet of agricultural labourers; and as toufu, or bean-curd. Bean refuse is well known as a fertiliser or as a fattener of hogs; bean oil as an illuminant is still preferred by thrifty Chinese to kerosene, as requiring no special lamp; and beancake, again, is familiar for fertilising and for the feeding of stock. But not so familiar is the use of bean oil for waterproofing umbrellas, and, when mixed with lacquer, for manufacturing varnish and printing ink. And yet further uses have been discovered for the bean in Europe. German millers experiment with it for the making of brown bread; English manufacturers produce excellent bean biscuits; it is sought for by makers of margarine, soap, candles, and for cheese; and French culinary ingenuity has even, according to reports received, employed the bean as a substitute for coffee beans.

With all these uses it is hardly to be wondered at that the increase in the export trade of soya beans has during the last three or four years been quite extraordinary, and that the bean has, to quote the Statistical Secretary's Report on the Foreign Trade of China in 1909, "taken at a bound a position equal to that of tea in the list of exports, and, with the addition of beancake, even challenges the position of silk at the top of the list."

ANTOINE WATTEAU. By Camille Mauclair. London: Duckworth & Co. 1s. net.

This little volume forms part of Messrs. Duckworth & Co.'s Popular Library of Art. Mr. Mauclair is a devoted admirer of Watteau, and the book perhaps acquires some additional interest from the writer's determination to regard the master's work in the light of the disease which cut him off in the fulness of his powers. There can be little doubt that an ailment like consumption must have a great effect upon the sufferer's mind and point of view, and the frequency with which it has been associated with great talent, and even genius, invested it at one time with something like a halo of romance. Mr. Mauclair claims to have had special opportunities for studying the effect of the disease upon the artistic imagination, and he attributes the ethereal, poetic dreaminess, which he sees more especially in the painter's later work, to "the unsatisfied yearning of a consumptive, who is chaste and wishes to remain so."

Mr. Mauclair gives a very readable account of Watteau's life, of his early struggles, his frightful poverty, of his sudden leap into fame and comfort, and of his almost equally sudden death. The volume contains over thirty illustrations. If some of them are smudgy and indistinct, the wonder is not that they are not better but that they are as good as they are at the price.

GENERAL NOTES.

TEXTILE EDUCATION IN BRADFORD.—The new textile department of the Technical College of Bradford was opened on October 25th by Lord Rotherham. The cost of the building and equipment is estimated at £35,000. A full course of instruction will be provided in wool scouring, top production, yarn production, warping, dressing, weaving, dyeing, and finishing. The machinery installed is of the very latest description, and students will have every opportunity of studying various kinds of motive power. The opening of the department marks a very important step in the development of technical education in Bradford.

TUNNEL UNDER THE ELBE AT HAMBURG.—The tunnel under the Elbe at Hamburg was opened to the public on October 7th. This work, which connects the city of Hamburg with the suburb of Steinwarender, situated on an island in the river, and with the left bank of the Elbe, is 428 metres in length (1,404 feet). It occupied four years in construction, at a cost of 10½ million marks (£525,000).

CANADIAN DIAMONDS.—The chief mineralogist of the Canadian Geological Survey for the past few months has been studying the olivine-bearing rocks of Canada, which often contain asbestos, chromite, platinum, and, in some cases, diamonds. Some of his examinations were into chromite ore from the Montreal pit, near Black Lake. Until 1910 this mine was worked for chromite, and he has established beyond all doubt that this ore contains an appreciable proportion of diamonds in small crystals. The discovery may prove of economic value. The diamonds are too small to be of use as gems, their size being microscopic, but there are so many of them that it is a question whether or not it would pay to separate them as a by-product in the concentration of chromite, and sell them as diamond dust, which is much used in the cutting and polishing of diamonds and other gems.

CHINESE TEA-SEED OIL.—Tea-seed oil is the name applied to an oil expressed from the seed of the Camellia Sasanqua. This is not the tea-tree (*Camellia Thea*), nor can its leaves be used. It grows principally in Honan, but is found wherever the wood-oil tree grows. The seeds are gathered

in October, and the extracted oil usually reaches the market in Hankow about the middle of winter. It is used by the Chinese as a cooking oil, and costs in the market from thirty-one shillings to thirty-three shillings per picul of 133⅓ pounds. Hankow's exports of this oil to foreign countries and Chinese ports in 1909 were valued at £6,500, and during 1910 at £17,300.

THE FRENCH TOBACCO MONOPOLY.—The latest statistics concerning the French tobacco monopoly show that the receipts of every nature in 1909 amounted to £19,000,000, an increase of £360,000 over 1908. The sales of manufactured tobacco for the year aggregated £18,800,000, and the net profits £15,300,000. The export sales represented less than £400,000 in value. The commissions, or profits of the retailers, who act as agents of the Government, amounted in 1909 to £1,600,000, or 8·47 per cent. of the sales. The sum expended in France for tobacco consumption during the year was 10*s*. 10*d*. per caput; the average tobacco consumption per caput was 36·6 ounces; the retailers numbered 47,669, or one to each 817 inhabitants. The tobacco production of France is almost equal to the importation. The 1909 figures were as follows:—Total yield, 27,134 tons; value of crop, £900,000; number of planters, 48,395; area cultivated, 37,156 acres; average yield per acre, 1,610 pounds.

CHINESE POMELOS, OR GRAPE-FRUIT.—Various kinds of pomelos are grown extensively in southern China, all of which vary more or less widely from the American grape-fruit, although belonging to the same family. Those grown in Amoy are the largest, and are regarded by foreigners as the best produced in China. A smaller kind is grown in the Foochow district, many of which are shipped to Amoy, there given the Amoy "chop," and then returned to Foochow as imported Amoy pomelos. The object of this, of course, is to give an inferior fruit the benefit of the Amoy reputation. The Amoy pomelos compare favourably with the American fruit in point of size, are thick-skinned, comparatively juicy, but decidedly bitter. The Chinese themselves prefer the Kwangsi pomelo, which is smaller but sweeter.

THE WILD POTATO OF CHILI.—Some excellent results have been obtained by Professor Heckel in the experimental cultivation of the *Solanum maglia*, or wild potato of Chili, at Saint Jerome, near Marseilles. In a communication to the Académie des Sciences, the professor states that each plant produced on the average two kilogs (nearly 4½ lbs.) of tubers, which are of a violet colour. The average weight of each tuber was 350 to 380 grammes (12 to 13½ ounces). The wild potato under cultivation is very hardy, and less liable to cryptogamous diseases than the common variety grown in Europe. Specimens of every known variety of the wild potato found growing in South America, both on the sea coast as well as at high altitudes in the Andes, have been obtained for further experiments.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, NOVEMBER 6...Engineers, at the Institution of Electrical Engineers, Victoria-embankment, W.C., 7.30 p.m. Mr. R. W. A. Brewer, "Two-cycle Engines."

Chemical Industry (London Section), at the Chemical Society's Rooms, Burlington House, W., 8 p.m. Dr. E. G. Acheson, "Deflocculation as affecting Lubrication."

Geographical, Burlington-gardens, W., 8.30 p.m. Dr. Fridtjof Nansen, "The Norsemen in America."

British Architects, 9, Conduit-street, W., 8.30 p.m. President's Opening Address.

London Institution, Finsbury-circus, E.C., 5 p.m. Mr. H. C. Bastian, "The Origin of Life Question."

TUESDAY, NOVEMBER 7...Alpine Club, 23, Savile-row, W., 8.30 p.m.

Civil Engineers, 25, Great George-street, S.W., 8 p.m. Address by the President, Dr. W. C. Unwin.

Photographic, 35, Russell-square, W.C., 8 p.m. Mr. W. T. Wilkinson, "The Difference in Reticulation of Gelatine obtained by the Use of various Chromates and Bichromates."

Zoological, Regent's Park, N.W., 8.30 p.m. 1. Mr. R. I. Pocock, "Lantern Exhibition on the Moulting of the Arctic Fox." 2. Mr. D. Seth-Smith, "On the Moulting of the King Penguin (*Aptenodytes pennanti*) in the Society's Gardens." 3. Mr. T. E. Gunn, "On the Presence of Two Ovaries in certain British Birds, more especially the Falconidæ." 4. Professor P. P. Sushkin, "Ontogenetical Transformations of the Bill in *Ardea cinerea*." 5. Dr. A. D. Imms, "On some Collembola from India, Burma, and Ceylon, with a Catalogue of the Oriental Species of the Order."

Horticultural, Vincent-square, Westminster, S.W., 3 p.m. Mr. J. Hudson, "The Cultivation of the Fig in Pots."

WEDNESDAY, NOVEMBER 8...Biblical Archæology, 37, Great Russell-street, W.C., 4.30 p.m. Rev. Dr. Ball, "A Study in Biblical Philology."

Geological, Burlington House, W., 8 p.m. 1. Professor Edward Hull, "On the Interglacial Gravel-Beds of the Isle of Wight and South of England, and the Conditions of their Formation." 2. Mr. J. B. Scrivenor, "The Gopeng Beds of Kinta, Federated Malay States."

Automobile Engineers, at the Institution of Mechanical Engineers, Storey's-gate, Westminster, S.W. Mr. H. E. Coffin, "Chassis Design."

Faraday Society, at the Institution of Electrical Engineers, Victoria-embankment, W.C., 8 p.m. Address, with Experiments, by Dr. E. G. Acheson.

Royal Society of Literature, 20, Hanover-square, W., 5.15 p.m. Lecture by Professor A. C. Benson.

THURSDAY, NOVEMBER 9...Child Study, 90, Buckingham Palace-road, S.W., 7.30 p.m. Professor W. Rippmann, "Psychology of Speech."

London Institution, Finsbury-circus, E.C., 6 p.m. Dr. Hans F. Gadow, "Life on the High Mountains of Mexico."

Camera Club, 17, John-street, Adelphi, W.C., 8.30 p.m. Mr. G. C. Druce, "Birds and Beasts in Ecclesiastical Architecture."

Electrical Engineers, Victoria-embankment, W.C., 8 p.m. Mr. W. T. Taylor, "Modern High Voltage Power Transformers in practice with special reference to a 'T' Three Unit System."

FRIDAY, NOVEMBER 10...Concrete Institute, 296, Vauxhall Bridge-road, S.W., 8 p.m. Presidential Address by Sir Henry Tanner.

Astronomical, Burlington House, 5 p.m.

Physical, Imperial College of Science, South Kensington, S.W., 5 p.m.

British Foundrymen's Association, Cannon-street Hotel, E.C., 8 p.m. Mr. F. J. Cook, "Physical Properties of Cast Iron."

Journal of the Royal Society of Arts.

No. 3,077. VOL. LIX.

FRIDAY, NOVEMBER 10, 1911.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.

NOTICES.

CANTOR LECTURES ON "BREWING."

The Cantor Lectures on "Brewing and Modern Science," by Professor Adrian J. Brown, M.Sc., F.R.S., have been reprinted from the *Journal*, and the pamphlets (price one shilling) can be obtained on application to the Secretary, Royal Society of Arts, John Street, Adelphi, London, W.C.

A full list of the Cantor Lectures which have been published separately, and are still on sale, can also be obtained on application to the Secretary.

ARRANGEMENTS FOR THE SESSION.

The Opening Meeting of the One Hundred and Fifty-Eighth Session will be held on Wednesday evening, November 15th, when an address will be delivered by LORD SANDERSON, G.C.B., K.C.M.G., I.S.O., Vice-President and Chairman of the Council. The chair will be taken at Eight o'clock.

The following arrangements have been made for meetings before Christmas:—

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock:—

NOVEMBER 22. — JAMES DOUGLAS, LL.D., Past President Am.Inst. Mining Eng., "The Industrial Progress of the United States of America."

NOVEMBER 29. — A. E. BERRIMAN, "The Efficiency of the Aeroplane."

DECEMBER 6.—J. A. J. DE VILLIERS, "British Guiana and its Founder, Storm Van 's Gravesande." LORD REAY, G.C.S.I., G.C.I.E., LL.D., will preside.

DECEMBER 13.—W. YORATH LEWIS, M.Am. Soc.M.E., A.M.Inst.Mech.E., A.M.Inst.E.E., "Continuous Service in Passenger Transportation."

INDIAN SECTION.

Thursday afternoon, at 4.30 o'clock:—

DECEMBER 14.—J. TRAVERS JENKINS, Ph.D., D.Sc., Superintendent of the Lancashire and Western Sea Fisheries, "Fisheries of Bengal."

CANTOR LECTURES.

Monday evenings, at 8 o'clock:—

PROFESSOR VIVIAN B. LEWES, "The Carbonisation of Coal." Four Lectures.

Syllabus.

LECTURE I.—NOVEMBER 27.—*The Composition of Coal.*—Existing theories on the composition of coal and the chemistry of its formation—Humus and resin compounds found in lignites, and the action of heat upon them—The classification of coals, and the effect of composition on the products of decomposition by heat—Coking and non-coking coals.

LECTURE II. — DECEMBER 4. — *The Methods Employed in the Destructive Distillation of Coal.*—The changes which have taken place during the last century in the forms and settings of gas retorts —The developments of the last ten years and present position of the gas industry—The coke industry and the gradual development of the modern recovery plant—The influence of the retort or oven on the carbonisation.

LECTURE III. — DECEMBER 11. — *The Thermal Conditions existing during the Carbonisation of Coal.*—The heat of formation of coal—The work of Euchene, Mahler, and others—The cause of the endothermic nature of some coals—The thermal value of the reactions taking place in the retort—The losses of heat in a retort setting—The transmission of heat through the retort and charge—The effect of temperature and travel on the primary products of decomposition — The temperatures existing in retorts and ovens—Small charges and

full charges—The influences which lead to improvement in the products from full charges, chamber and vertical retorts.

LECTURE IV. — DECEMBER 18. — *The Possible Improvements in Carbonisation.*—The aims of the gas manager and coke producer—Experiments on low temperature distillation and their teaching—The rivalry existing between fully-charged retorts, vertical retorts, recovery ovens, and chamber carbonisation — The intermittent vertical retort *versus* the continuous vertical systems—The Settle-Padfield, Duckham-Woodall, and Glover-West processes—The ideals of carbonisation—The volume of gas due to primary and secondary reactions—The gasification of tar—The limitations of volume and quality of gas—The ends to keep in view in devising new processes of carbonisation.

Papers to be read after Christmas:—

CECIL THOMAS, "Gem Engraving."

F. MARTIN DUNCAN, "The Work of the Marine Biological Association."

H. A. ROBERTS, M.A., "The Relations of Science to Commerce and Industry."

JOHN NISBET, D.Oec., late Conservator of Forests, Burma, "The World's Decreasing Timber Supplies."

FRANK WARNER, "Silk."

CHARLES C. ALLOM, "The Development of Artistic Skill in the Applied Arts."

CYRIL DAVENPORT, "Illuminated MSS."

ERNEST KILBURN SCOTT, A.M.Inst.C.E., M.Inst.E.E., "The Manufacture of Nitrates from the Atmosphere."

CHARLES BRIGHT, M.Inst.E.E., "The Administration of the Imperial Telegraphs."

HAROLD COX, "The Interdependence of Morals and Economics."

PROFESSOR G. W. OSBORN HOWE, "Recent Progress in Radio-Telegraphy."

E. D. MOREL, "British Rule in Nigeria."

GORDON CRAIG, "Stage Illusion."

THEODORE E. SALVESEN, "The Whaling Industry of To-day."

LEONARD HILL, M.B., F.R.S., and MARTIN FLACK, M.A., M.B., B.Ch., "The Influence of Ozone in Ventilation."

E. A. GAIT, I.C.S., C.I.E., Census Commissioner for India, "The Indian Census of 1911."

WALTER SAISE, D.Sc., M.Inst.C.E., F.G.S., "The Coal Industry and Collier Population of Bengal."

NEVILLE PRIESTLEY, Managing Director, South Indian Railway, "Indian Railways."

W. A. LEGG, M.Inst.C.E., "Irrigation in South Africa."

ALAN BURGOYNE, M.P., "Colonial Vine Culture."

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock:—

January 18, February 8, March 14, April 25, May 16.

COLONIAL SECTION.

Tuesday afternoons, at 4.30 o'clock:—

January 30, February 27, March 26, May 7.

CANTOR LECTURES.

Monday evenings, at 8 o'clock:—

VAUGHAN CORNISH, D.Sc., F.G.S., F.C.S., "Ocean-Waves, Sea-Beaches, and Sandbanks." Two Lectures.

January 22, 29.

LOUDON M. DOUGLAS, "The Meat Industry." Three Lectures.

February 5, 12, 19.

LUTHER HOOPER, "Hand-Loom Weaving." Three Lectures.

February 26, March 4, 11.

NOEL HEATON, F.C.S., "Materials and Methods of Decorative Painting." Three Lectures.

March 18, 25, April 1.

HOWARD LECTURES.

Monday evenings, at 8 o'clock:—

CAPTAIN H. R. SANKEY, R.E., M.Inst.C.E., "Heavy Oil Engines." Four Lectures.

April 29, May 6, 13, 20.

JUVENILE LECTURES.

Wednesday afternoons, at 5 o'clock:—

CHARLES VERNON BOYS, F.R.S., "Soap Bubbles." Two Lectures.

January 3, 10.

EXAMINATIONS, 1911.

During the past year the subject of the value of examinations has come in for a good deal of discussion. This discussion was first started by Mr. Philip Hartog in the paper he read here on "Examinations in their Bearing on National Efficiency," and the value of Mr. Hartog's original paper was greatly enhanced by the remarks, equivalent, indeed, to a supplementary paper, by Lord Cromer from the chair. The discussion was continued at the last meeting of the British Association. Sir William Ramsay devoted a considerable portion of his presidential

address to the consideration of the value of examinations, and Dr. Welldon, in his address as President of the Educational Section, discussed the matter at still greater length, whilst Mr. Hartog himself carried the discussion a little further in a paper on "The Place of Examinations in Education," before the same section.

The consideration of the subject was, however, for the most part confined to the value of competitive examinations as a test of a candidate's qualifications for some particular post. The general result arrived at was much the same as had been acknowledged long before —that competitive examinations are a necessary and inevitable evil; an objectionable device for deciding the relative merits of candidates, which has to be retained until something better can be put in its place. In rare instances, such as the one mentioned by Lord Cromer, a substitute can be found. But when it comes to selecting a number of candidates for Government posts, it is a choice between favouritism and examination; and the latter system, on the whole, is the more popular, though it is a matter for argument which of the two systems provides the better results.

The examinations with which the Society is concerned are, of course, of a different class. The Society's examinations form part of an enormous system, the extent of which is, perhaps, hardly realised. It may be interesting to give some figures illustrative of the work done by the various bodies which undertake to provide examinations of a moderate standard in the various branches of knowledge.

These figures are taken from official sources, but are not official. It is probable that they are not wholly accurate. They are certainly not wholly complete. For instance, the Scotch Education Department hold annual examinations for their Intermediate and School-Leaving Certificates. In 1910, 4,093 of the former and 1,080 of the latter were awarded, but the numbers of the candidates are not published. At any rate the figures here given may serve as an indication of the number of students examined during the year 1910.

NUMBER OF CANDIDATES EXAMINED IN 1910.

Lancashire and Cheshire Union of Institutes—		
Ordinary	25,918	
Course	15,821	
		41,739
		271,794

We thus get a total of 271,794 examinees. If to this we add the 27,330 examined by the Society in 1910, we have a total of 299,124—say, 300,000 candidates examined in elementary and secondary subjects during the year. To this must be added the results of all the university and professional examinations, and of all the competitive examinations for the Army, Home and Indian Civil Services, etc.

These figures certainly show that there is an enormous demand in this country for examinations, and that the demand is fully supplied. Most people will admit that whether examinations are, or are not desirable, the thing is

somewhat overdone. Whether all this examination is a good thing or a bad thing, there is no doubt an increasing feeling of dislike to it, and we are now probably at the stage of reaction against over-examination.

There are two points in which examinations have, or may have, a value—first, as a test of knowledge; and, secondly, as an incentive to the acquisition of knowledge. As to their value as a genuine test of knowledge, it is rather difficult to form an opinion. They can only test the information there is in the candidate's head at the moment, and in too many cases that information has acquired but a temporary resting-place there. An examination is, probably, a better test of a candidate's power of acquiring knowledge than it is of the amount he possesses, and perhaps that may be considered as an argument in its favour. As a matter of fact, the question cannot be answered in general terms. Perhaps no better test need be desired of a man's mathematical knowledge than the mathematical tripos at Cambridge. But an elementary examination in physics or chemistry, or indeed in most other subjects, offers but a poor means of estimating the real amount of knowledge possessed by a candidate. But it must always be remembered that on the whole a student who has passed an examination is probably a little better informed and a little better instructed than one who has failed, and if the possession of an elementary certificate does not amount to a great deal, at all events it means something.

As an incentive to the acquisition of knowledge, it is evident that the present system of examination has its value; its enormous extent alone is sufficient to show that. There are very few such earnest students as to be satisfied with the acquisition of knowledge for its own sake, and in the case of most people, especially of young people, an artificial stimulus is required. This stimulus, it is found, can very satisfactorily be provided by hall-marking those who have passed an examination, and allowing them to bear some special title—as "Dr." or the like—or permitting them to attach certain initials to their names.

There is, therefore, a good deal to be said in favour of general examinations, although there is a good deal to be said against them on the score of the superficiality of the knowledge that they tend to produce, and also on account of the very erroneous idea that has been disseminated that the fact of a student having passed an examination is any evidence whatever of his possessing a knowledge of the subject examined in. On the whole, we have got the system firmly established, though perhaps it is rather overgrown and wants pruning. But the important question is to make the system as good and as practically useful as may be.

With regard to the Society's examinations, it has always been a question whether the system adopted of holding separate examinations in separate subjects is the best, or whether it is better to classify the subjects, and only issue certificates on the result of an examination held in a number of specified subjects. The experience of the Society certainly shows that the system of separate examinations is the more popular, and there is much to be said as to its actual merits. The arguments in its favour were very strongly put by Professor Huxley many years ago in an address which he delivered on the occasion of the opening of the Johns Hopkins University at Baltimore. He said: "It (the system of separate subject examinations) allows the student to concentrate his mind upon what he is about for the time being, and then to dismiss it. Those who are occupied in intellectual work will, I think, agree with me that it is important, not so much to know a thing as to have known it, and known it thoroughly. If you have once known a thing in this way, it is easy to renew your knowledge when you have forgotten it; and when you begin to take the subject up again, it slides back upon the familiar grooves with great facility."

It may also be mentioned that the attempts which have been made at different times by the Society to issue a combined certificate have not been very successful, and the demand for the certificate of that sort which is now offered is extremely small.

The examinations this year were held at 459 centres in the week commencing April 3rd, and lasted from the Monday until the following Friday. The results were issued at the following dates:—Advanced Stage, July 6th; Intermediate Stage, August 2nd; Elementary Stage, September 7th. Having regard to the very large numbers of papers to be dealt with, no prospect can be held out of the results being issued at earlier dates.

The Commercial subjects included Book-keeping, Accounting and Banking, Shorthand, Typewriting, Economics, Précis-writing, Commercial Law, Commercial History and Geography, Arithmetic, Handwriting, Commercial Correspondence, etc. (added to the list this year), and Modern Languages. The other subject of examination was Music, divided into Rudiments of Music and Harmony.

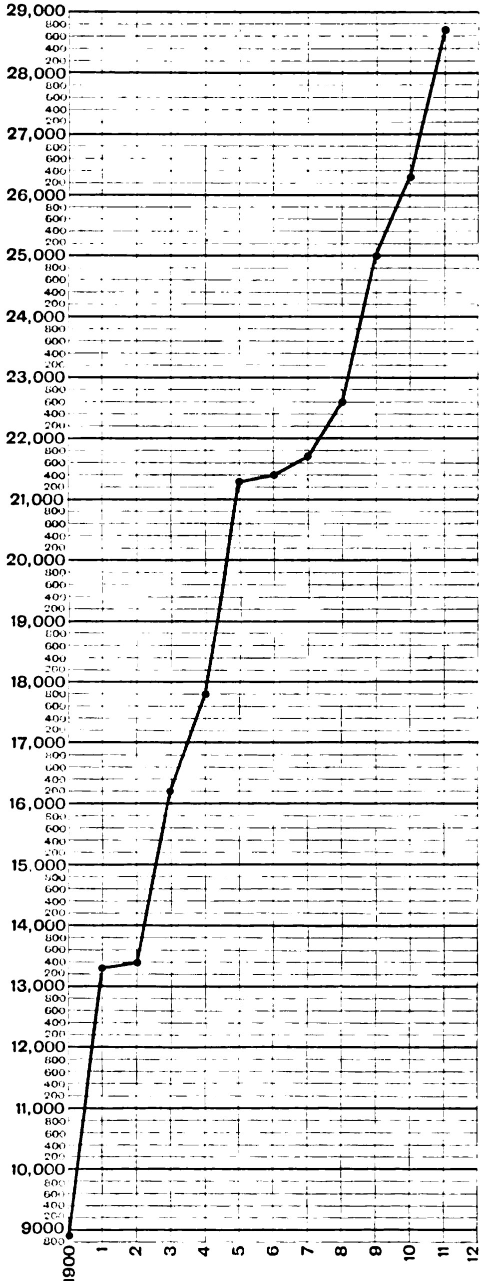
The Society this year awarded twenty-six Silver and forty-seven Bronze Medals, the former in the Advanced Stage, and the latter in the Intermediate. It also gave away money prizes to the value of £104, besides the prizes, amounting this year to £18—since some were not awarded—provided annually by the liberality of the Clothworkers' Company.

The total number of candidates at the examinations of 1911 was 28,644 (Advanced, 5,134; Intermediate, 12,233; Elementary, 11,277). This is an increase of 2,361 upon the 26,283 candidates of 1910. All the three Stages show larger numbers. In the Advanced Stage there was an increase of 480. In the Intermediate, an increase of 893. In the Elementary an increase of 988. These figures are even more satisfactory than those of last year, when there was a very large growth in the Elementary and a falling off in the Advanced Stage. The number of papers worked by these candidates was: Advanced, 5,931; Intermediate (including Theory of Music), 14,025; Elementary, 14,286, or 34,242 papers in all. In addition to this there were sixty-four Shorthand candidates at the Special Army Examination. In addition to these, again, there were 583 candidates in Colloquial Modern Languages, and 283 in the Practice of Music. The total number of candidates who were examined in all subjects by the Royal Society of Arts during the year ending July last was, therefore, 29,574. The general results of this year's examinations are given in Table A (page 1134), and a comparative view of the numbers examined during the last six years (1906-11) is given in Table B (page 1136). Table K (page 1142) gives the totals of the Commercial and other examinations for the same period, and Table G (page 1138) the numbers of papers worked. The diagram on this page shows the rate of growth from 1900 to 1911.

Considering the total number of papers worked in all Stages (34,242), Book-keeping proves the most popular (11,153); then Shorthand (7,872). None of the other subjects attract anything like these numbers; but French has a large entry—3,647. Of late years there has been a very great increase in the number of candidates taking up French, and this is a very satisfactory sign—the increase being well kept up this year. Arithmetic follows with 2,741; next is Typewriting, with 2,412; Handwriting and Correspondence (Stage I. only), has 1,742. Then there comes German with 994, and Commercial History and Geography 532 (in the Elementary Stage the subject appears as Commercial Geography alone). Accounting and Banking (Stage III. only) has the next largest number with 499. Then comes English with 485. The new subject, Commercial Correspondence and Business Training (in Stage II. only) makes a



good start with 303. The numbers for Spanish were 278, Commercial Law (Stage III. only), 247, Précis-writing 362, a large increase on previous years, and Economics 138. The entries for the other subjects were not very large.

1909	5,433	12,512	11,069	29,014
1910	5,309	12,843	12,720	30,872
1911	5,931	14,025	14,286	34,242

The numbers for Stage II. include the papers set in Music.

In the Advanced Stage nearly all the subjects show an increase, in most cases small. In two only the increase is important—French, in which there were 160 more papers than last year, and Book-keeping with an addition of 216. There was an increase of 92 in Accounting and Banking, 10 in Commercial Law, 43 in English, 29 in Arithmetic, 22 in Commercial History and Geography, 52 in German, and 31 in Précis-writing. Shorthand and Spanish are practically the same as last year, there being one more in the former and one less in the latter. The numbers in the other subjects are small, the differences between this and last year's results being negligible.

In this Stage, Book-keeping is by far the most popular subject, the number of papers worked being 2,265. French comes second with 967, then Shorthand with 867. The number of French papers has increased largely of recent years. Last year the subject stood third, Shorthand coming second. Accounting and Banking follows with 499, then Typewriting with 222. The subject of Accounting and Banking was introduced in 1905, and the numbers entering for it have increased regularly year by year. Commercial Law, which was added to the list of subjects in 1905 also, has 247 entries. German has increased, and there were 212 papers worked in it.

In the Intermediate Stage also nearly all the subjects show an increase over the numbers of last year, three only showing a falling off. In Commercial History and Geography there is a deficiency of 33, in Shorthand of 120, and in Spanish of 31. All the other subjects have grown in numbers. Shorthand is the most popular subject in this Stage, with a total of 4,344. Book-keeping with an increase of 438, and a total of 4,287, is very close, and will probably take the lead another year. The third largest subject is French with 1,488 entries, 205 above last year. Typewriting comes next with 887, and a small increase of 38. In Arithmetic there were 731 and a large proportional increase of 93. In German there were 354, only 37 more than in 1910. The numbers in English were nearly the same, 351, 10 more than last year. The new subject —Commercial Correspondence and Business Training—attracted 303 candidates, which was very good for a beginning. The candidates for Précis-writing were twice as numerous as in the previous year, 268, with an increase of 139. It is unsatisfactory that there should be so considerable a proportionate diminution in number of candidates in Spanish, there having been only 90 as compared with 121 in 1910. Though the number in Italian is not very large, 28, it is just double what it was last year. For Economics there was a small increase of 15. In Portuguese 3 more were examined than last year. There were a few candidates in Russian, Hindustani, Danish and Norwegian, Swedish and Japanese—none in Chinese.

In the Elementary Stage the 11,277 candidates worked 14,286 papers, so that, as is always the case, a large proportion of the candidates in this as in the higher stages, were content with a single subject.

The largest number is Book-keeping—4,601, an increase of 785 over last year; then Shorthand 2,661, a decrease of 75; Arithmetic 1,833, an increase of 231; Handwriting and Correspondence 1,742, an increase of 552; Typewriting 1,303, an increase of 172; French 1,192, a decrease of 162; German 428, an increase of 14; and Commercial Geography 401, an increase of 29. The other two subjects are Spanish 107, an increase of 27, and Italian 18, a decrease of 7.

In all, 9,242 certificates were granted to successful candidates, and there were 5,044 failures. The percentage of success (64·69) is not quite so good as last year (66·80), or the year before (66·54), and this is to be regretted. It rose steadily from 59·39 in 1906, and it is difficult to understand why the improvement should have ceased. Figures relating to the Elementary Stage for the past eleven years are given in Table F (page 1138), and the percentages of successes and failures for the last six in Table E (page 1138).

The number of centres at which the examinations are held has increased with the growth of the examinations, and during the last seven years in rather larger proportion than the number of candidates. In 1905 there were 383 centres. This year there are 459. Of these, 346 were in England and Wales, 48 in Scotland, 64 in Ireland, and one in the Channel Islands (Guernsey).

The different subjects in the two higher Stages may now be considered a little more in detail. The percentages of success and failures in each subject in the two higher Stages are set out in Tables C and D (page 1138), and the general percentages for the last six years in Table E (page 1138), Table H (page 1140), and Table I (page 1140).

In Arithmetic there is a satisfactory increase in the number of entries, both in the Advanced

Table H.

and Intermediate Stages; but though the percentage of failures is lower in Stage II. it is higher in Stage III. This fact corresponds with the remark of the examiner that the number of first class candidates has not increased in quite the same proportion, and that some of the candidates would have been better advised to defer taking this paper until they were more fully prepared. Still there was a considerable amount of sound and intelligent work, including some really excellent papers. Of the entries in the lower grade he also remarks that a great many are not nearly up to the standard of the grade.

In English also there was a considerable increase in the number of papers, and, as far as can be judged from percentages, the standard of the papers is much about the same as last year. The general results of the examination are reported as encouraging. A satisfactory feature in Stage II. is that a larger percentage of the candidates obtained first-class certificates.

In Book-keeping there is in both Stages a considerable increase; but this increase in numbers is not accompanied by a corresponding increase in quality. In both Stages the results are distinctly less good than last year or the years preceding.

In Commercial History and Geography the numbers examined show an increase in Stage III. and a decrease in Stage II. Although the percentage of failures was higher in both Stages, the examiner speaks well of the work. Though he does not find in Stage III. a corresponding rise in the quality of the work done, he thinks that in Stage II. there was a very marked improvement in the general character and standard of the work.

In Shorthand the number of candidates in Stage III. was practically identical with last year. In Stage II. there was a trifling falling off. In the Advanced Stage there is a decided advance in the first class, but a drop in the second class, and an increase in the proportion of failures. The diminution in the second class is to be accounted for by the alteration in the rules. Up to the present year a candidate failing in the first class paper might, at the discretion of the examiner, be awarded a second-class certificate. But on the whole this plan did not appear to give satisfaction, and it was altered in the examinations last held. In spite of this alteration, however, the numbers both of first and second class papers in Stage II. show an increase, and there is a proportionate decrease in the number of failures. The quality of the work in this Stage has, in the examiner's opinion, shown a decided improvement.

In Typewriting there were a few less papers worked in Stage III. and a few more in Stage II. The percentage calculations show an improvement in both Stages, and this agrees with the comments of the examiner, who finds a gratifying improvement of recent years both in the quality and the quantity of the work submitted.

In Economics there is a smaller entry in Stage III., but a larger one in Stage II. The examiner expresses regret that in the Advanced Stage the quality of the work shows a falling off as compared with last year; but, on the other hand, in the Intermediate Stage, the work as a whole has improved since last year. This opinion is confirmed by the percentage of failures, which is greater in Stage III. and less in Stage II. The conclusion to be drawn from this fact is that a number of candidates as usual make the mistake of entering for the Advanced Stage who are only capable of dealing with the Intermediate paper.

In Précis-writing there was a small increase in the Advanced Stage, and a very large increase in the Intermediate. In the opinion of the examiner the work in Stage III. was quite up to the average of recent years. In Stage II. the proportion of first class candidates was unduly small.

In Commercial Law there is again a slight but satisfactory increase in the number of candidates, but only a small proportion of papers were good enough to reach the first class standard, and the percentage of failures was larger than usual. The best papers sent in this year were not quite up to the rather high standard which has been maintained by the medallists in previous years.

In Accounting and Banking there was a large addition to the numbers of last year. There has been a steady and continuous increase since the examination was established, and the number has nearly doubled itself since 1908. The percentage of first class is higher than in any previous year. Although the percentage of passes is rather lower than last year, the average of work on the whole compares favourably with that of previous years.

The increase in the number of candidates for the French examination is one of the most remarkable features in the statistics of the examinations of recent years. In Stage III. the percentage of failures is higher, but it is lower in Stage II. On the whole, the examination in both classes has given satisafctory results, and

the general standard appears to have been maintained.

It is a little remarkable that while in other quarters there are complaints of want of attention being paid in this country to the study of German, the numbers entering for the Society's examinations in that subject by no means confirm such a view, as there is an increase in both Stages; and the examiner reports that it is evident that an increasing number of students are reading German with intelligence and profit. The improvement noted last year has been well maintained.

The examiner in Italian speaks well of the work submitted in both Stages.

The examiner in Spanish considers the work in Stage III. satisfactory as regards the majority of the candidates, though a good many had not the least right to attempt such a high standard. On the other hand, the work of the candidates in Stage II. was well up to the standard required.

In Portuguese there is no sign of improvement, rather the contrary. The numbers show a slight decrease, and the standard is distinctly lower.

With regard to the other language examinations there is not a great deal to be said. The numbers are much too small for any general conclusions to be drawn from the results. Where so few candidates enter it has generally been considered desirable to keep the standard down, with a view of encouraging students to enter; but in some cases the utmost leniency has not sufficed to justify the passing of some of the candidates.

With reference to the new subject added this year to the Intermediate Stage—Commercial Correspondence and Business Training—both the number of entries and the results may be regarded as quite satisfactory. It was thought well that for the first year considerable leniency should be shown, and the standard was kept as low as was consistent with justice. After a few years it will certainly be expected that to obtain a first-class certificate candidates will have to display a higher standard of knowledge.

For the Viva Voce Examinations held this year in Modern Languages 583 candidates entered—a decrease on last year, when there were 642. These examinations were started in 1902, when 280 candidates were examined. The numbers rose to 681 in 1905, after that there was a slight falling off. Examinations were held this year in French, German, Spanish, and Italian; there have also in previous years been a few entries for Portuguese, but none entered during the last three years. The numbers were: French, 426; German, 110; Spanish, 37; Italian, 10. Table L (page 1142) gives in detail the results of this year's examinations.

The examiner in colloquial French reports that the examination was in no way below the level of its predecessors. The German examiner again says that though the number of candidates examined was smaller than in 1910, the percentage of successes was higher, and considers that the general results were extremely satisfactory. The results in Spanish are still rather unsatisfactory, though a little better than last year; the numbers entering were a little larger, and the proportion of failures was smaller. Though the numbers entering in Italian is never very large, the candidates appear to be better taught, and the proportion of failures is always very small.

The examinations in Rudiments of Music and Harmony were carried on as usual at the same time as the Commercial examinations, and the results appeared as part of the results of the Intermediate Stage. The total number of candidates shows an increase as compared with last year. This year there were 691, compared with 619 in 1910, 699 in 1909, 716 in 1908, 641 in 1907, and 637 in 1906. In Rudiments of Music, 398 candidates presented themselves, whereas last year there were 377. In Harmony there were 293, as compared with 242. Of the 398 candidates in Rudiments of Music, 337 passed and 61 failed. Of the candidates in Harmony, 224 passed and 69 failed. The examiner, on the whole, reports favourably on the results, which do not differ very much from those of recent years.

A report on the Practical Examinations in Music has been published in the *Journal*.* 283 candidates were examined—a decrease of 56 as compared with the 339 last year; of these 214 passed and 69 failed. These examinations have been carried on continuously since they were established in 1879. The numbers for a long time did not vary very widely. In the first year 117 candidates were examined. The numbers increased gradually to 276 in 1891, and to 393 in 1895. The largest number yet examined was 566 in 1900. During the last few years there has been a small but steady diminution in the numbers. The standard has not varied much, but is now a little higher than it was. The general level of attainment is considered by the examiners to be about the same as for the last few years.

---

* See *Journal*, July 21st, 1911, Vol. LIX. p. 869.

At the request of the Army Council, the Council, in 1907, arranged to hold a special annual examination in Shorthand for soldiers, and such an examination has been held every year since. In 1907 there were 40 candidates; in 1908, 84; in 1909, 60; in 1910, 66. This year there were 64 entries. There were 26 centres in the United Kingdom, India, South Africa, and Egypt. These examinations were held on March 30th. Of the 64 candidates, 47 passed and 17 failed. In the Advanced Stage there were 7 second class, but no first. In the Intermediate Stage there were 15 first and 25 second. The percentage of successes is a little over 73, which is not as good as last year, which was 82. Still this is much above the average of Shorthand examinations.

The Examination Programme for 1912 was issued three weeks ago. In it will be found the fullest possible information about the Examinations, a syllabus of each Stage of each subject, and the papers set in 1911. The attention of both teachers and students may be drawn not only to the syllabuses but also to the remarks of the various examiners on the results of last year. It will be found that these contain many valuable and helpful suggestions, and the work of the candidates year after year shows that far too little attention is paid to them. Teachers especially should study these remarks, and be guided by them in the instruction they give to their pupils. The remarks of each examiner follow his examination paper in the Programme for each year.*

The regulations for the Examinations in Music (Theory and Practice), and those for the Viva Voce Examinations in Modern Languages, are also given at full length.

COTTON-GROWING IN ERITREA.

As one of the aims of the Italian Government in the development of their African colony of Eritrea is the keen desire to give to the cotton industry, at present largely dependent on American cotton, a new, and what might be called "home" supply of the raw material, much importance is attached to the proposal to cultivate cotton on a large scale in Eritrea. Investigations have proved that about 90,000 acres can at present be utilised for such cultivation without any special preparation of the soil, and an additional 125,000 acres if advantage be taken of the natural inundations. With the construction of the hydraulic works, already studied and planned out, for the irrigation of the plains of Tessenei and the valley of the Barca, a much larger area can eventually be adapted for the growing of cotton. It is estimated that the two areas are capable of producing 264,000,000 pounds of cotton annually. A Milan concern, which holds a concession for the cultivation of cotton in Eritrea, has already two ginning plants in the colony—one at Agordat, and a less important one at Massowah. From about 2,300 acres conceded to this company, a production of 2,200,000 pounds was expected in 1911. This is not a notable quantity, but the small production is due largely to the cost of transportation. This is the most important question in the economic development of the colony, and the Italian Government proposes to extend the present railway line from Massowah to Asmara (now nearly completed) as far as Keren, a farther distance of about sixty miles. With this line in operation, the products of the valley of the Barca will be brought by rail to the port of Massowah in five days, instead of the eighteen days by camel as at present. The Ministerial project meets with general favour, and it is believed that the extension will be built, and in operation, within the next two years.

THE USE OF ELECTRICITY IN NEW ZEALAND.

The demand for electricity in New Zealand for industrial purposes, such as for factories, mining, tramways, street lighting, and for domestic lighting, heating, and cooking, is increasing constantly. The public has become so educated to electricity, that the need for its cheap development by water power is well recognised by local government authorities, who now feel that unless they are prepared to permit private capital to establish water-power works, they can no longer refrain from committing themselves to the necessary expenditure and risks. At present, according to the American Consul on special service in New Zealand, 1,320,000 units of electricity are sold annually for electric lighting in Wellington, 742,000 in Dunedin, and 369,620 units in Christchurch. In Auckland electric lighting has just been introduced. In all these cities, except Dunedin, electricity is now produced from coal. Electric street lighting is already fairly well developed in Wellington and Dunedin, 562,000 units being used last year in Wellington, and 102,000 units in Dunedin. In Auckland one road has been successfully lighted with flame arc lamps, and no doubt the system will be extended to all the main thoroughfares. In Christchurch street lighting by electricity has not yet been attempted, except for a few arc lamps maintained at the tramway stopping places. The Minister of Public Works estimates that within the next five years, owing to the introduction of

* The price of the Programme (136 pages) is 3*d*., post free 4½*d*. Copies can be obtained on application to the Secretary of the Royal Society of Arts, Adelphi, London, W.C. Programmes containing the papers set in 1905, 6, 7, 8, 9, 10 can also be obtained at the same price. The regulations and syllabuses can also be had separately (without the papers) price 1*d*., by post 1½*d*

cheap electric power, Wellington will have 190 miles of streets lighted with 220 electric arcs and 2,000 electric glow lamps; Auckland, 150 miles lighted with 200 electric arcs and 500 electric glow lamps; Christchurch, 170 miles lighted with 220 electric arcs and 400 electric glow lamps; and Dunedin, 180 miles lighted with 240 electric arcs and 600 electric glow lamps. It is stated, on the same authority, that the demand for electricity as a domestic utility will probably be as great as for electric lighting. It is estimated that within five years' time there will be 4,200 electric stoves and heaters used in Wellington, 3,200 in Auckland, 3,100 in Christchurch, and 3,200 in Dunedin. Among the electro-chemical industries suggested for New Zealand in connection with its water power is the manufacture of calcium carbide, the imports of which are increasing each year. Probably of still greater importance to New Zealand is the possibility of electric smelting of iron and steel, as the country is fortunate in having iron deposits, and the necessary limestone flux within easy distance of extensive water power.

HOME INDUSTRIES.

The Crops.—The preliminary statement showing the estimated total produce and yield of crops in 1911 has just been issued by the Board of Agriculture and Fisheries, and shows that the wheat crop of 1911, amounting to 7,832,196 quarters, is the largest returned since 1899, and exceeds by nearly one million quarters the crop of last year. The yield per acre was one and one-seventh bushels (3·6 per cent.) above the average of the preceding ten years, and two and a half bushels more than in 1910, though smaller than in 1909 by nearly one bushel per acre. Each of the other crops is more or less below average. The yield of barley was one and a half bushels per acre below average, and the total crop is more than a million quarters less than the average, and smaller than in any previous year on record. Oats were over two bushels per acre short of an average, and the total crop is less than in any year since 1901. Beans were five bushels per acre below average, and, notwithstanding a substantially increased acreage, gave a total crop of 120,000 quarters less than in 1910. The yield of peas was slightly better than in 1910, but nearly a bushel per acre below average. Clover and "seeds" hay yielded 5 cwts. per acre, or 16 per cent., below average, while meadow hay gave little more than three-fourths of an average. The total crop of clover and "seeds" hay is the smallest since 1893, and of meadow hay the smallest since 1901. Altogether, the hay crop of 1911, amounting to 7,183,240 tons, is 2,333,000 tons less than that of 1910, and about 20 per cent. below the ten years' average.

The Cotton Crop.—Messrs. Hubbard Bros. & Co., who are amongst the most careful of American commentators on the affairs of the cotton market, support by anticipation Messrs. Neill's estimate of a 15,000,000 bale minimum crop. They write: "It now looks as though the crop would exceed 15,000,000 bales, and no one knows what such a crop is worth, but that is a chance the speculator must take. The question is—Is he ready to take it now? We do not see that he is, but we note his inquiries." The inquiries referred to here are from those who are waiting a favourable opportunity to buy cotton as an "investment"—that is, with a view to holding it indefinitely for a substantial rise. Messrs. Hubbard think that if trade conditions were better, and the troubles in Tripoli and China were at an end, speculative buying might become a feature of the market. However that may be, the probabilities point to an American cotton crop of unexampled proportions. It may be taken as certain that the crop will be close upon 15,000,000 bales, and may well exceed those figures. The highest previous record was 13,566,000 bales in 1904–5. Low prices would, therefore, seem to be assured, although we may be sure that American manipulators will do what they can in the way of holding back the surplus supply and curtailing next season's acreage to keep up prices. During the past four weeks the quoted decline was fifty-six points, making a difference of 2½*d.* per lb., or 33 per cent. in the price of the raw article as compared with last year. The position of the spinners is in pleasant contrast to what it was in the last two seasons, and though the civil war in China, and threatened coal strikes and railway strikes at home, are adverse counters, it is reasonable to anticipate that the present improvement in the textile trade will be maintained.

The Crown Agents and the Middleman.—It is the practice of the Crown Agents for the Colonies to deal only with actual manufacturers. In this way they eliminate the middleman. An attempt is now being made to induce the Department to vary this practice and to recognise the merchants. It is contended that they are often in a position to offer better terms than the manufacturer. Often they have large stores of the article required, and would supply requirements forthwith. Then they are more familiar with local conditions, and experience has given them a greater aptitude for securing exactness in the work required, than a manufacturer who is concerned with no particular market. Again, the Crown Agent, buying in the colony, or from merchants here who would sell on c.i.f. terms, would know exactly what he was paying, whereas by buying from the manufacturer he is not aware of the exact cost to the colony until he has calculated the cost of packing, insurance, and freights. And yet again, the merchant contends that he is better acquainted than the manufacturer can be with the terms imposed by law as to the make up and marking of goods. The arguments in favour of the merchant being allowed to tender would seem to be weighty.

Rubber Supplies.—It seems likely that the cultivation of Ceara rubber on the Upper Blue Nile will

be carried on successfully, and that a good deal of wild rubber will be got from the Bahr-el-Ghazal province. The Imperial Institute furnished reports during 1910 to the Government of the Sudan on Landolphia and Ceara rubber on the basis of investigations conducted in the scientific and technical department, followed in some instances by submission of samples to manufacturers and experts for technical trial or valuation. The report gives details of two consignments. A small consignment of rubber from the Bahr-el-Ghazal, derived from the indigenous vine, was forwarded for examination and subsequent sale. The rubber was in the form of biscuits and sheet, varying from light to dark brown; it was of good quality and contained from 92·7 to 93·6 per cent. caoutchouc in the dry material. The consignment, weighing 647 lbs., was divided into four lots and sold in London at prices ranging from 6*s.* 9*d.* to 8*s.* 4*d.* per lb. Brokers reported that the rubber was exceptionally strong, and that prepared with a little more care it should realise prices comparing favourably with those of Eastern plantation rubbers. A sample of Ceara rubber, derived from two-year-old trees at Mongalla, consisted of clean biscuits of pale yellow rubber which exhibited good physical properties. Great care had been used in the preparation. It was not quite as good in composition as specimens of Ceara rubber from Ceylon, but it was superior to several samples from East Africa which have undergone examination at the Imperial Institute.

The Insurance Bill.—It may be taken as certain that the Insurance Bill will become law before the end of the year, unless the House of Lords rejects it. The Ministerial majority is unshaken, and, with the closure, will enable Ministers to carry the measure. Some of its more glaring anomalies have been removed or lessened, but it is to be feared that in its final form it will be very faulty. Perhaps that was inevitable, having regard to the conflicting and varied interests with which it deals, but more prolonged discussion than it will receive was necessary to make the measure one that might be regarded without deep anxiety as to its effect when in operation. For example, an amendment was moved, the intention of which was to prevent approved societies selecting certain cases for insurance and rejecting others at will. Mr. George opposed it. In doing so he said that the societies would depend for their success upon good management, which is true enough; but he went on to say that such good management would be shown not in a careful selection of good, healthy, insurable persons, but in the rigorous examination of claims for sick benefit, and that even a doctor's certificate to the effect that the applicant was sick must not be accepted as *prima facie* evidence that the sickness was *bona fide*. The reader interested in the matter should refer to the official parliamentary report for Mr. George's exact words; the above is their purport. But they will not bear examination. The Bill makes the society responsible for excessive sickness, and excessive sickness means one of two things, either an additional levy or reduced benefits. But the first factor in producing a sickness claim not in excess of the actuaries' expectation, is the careful scrutiny and selection of new entrants. And any society which refuses to pay sickness benefit upon the medical certificate of qualification for it will act unlawfully. In such a case the medical evidence must be absolute, but Mr. George thinks otherwise. In his opinion the evidence must be judged "ruthlessly." You are to accept the workman's proposal and his money, in return for which you give him a contract to pay certain benefits, and then you are to set up a standard of your own by which to decide whether the benefits shall be paid or not.

Canadian Immigration.—During the last ten years Canada has received nearly 2,000,000 immigrants, of whom approximately 750,000 were from the United Kingdom and 700,000 from the United States. Up to the close of the fiscal year ended March 31st, 1911, the total was 1,714,326 for the decade. Since then nearly 200,000 more have arrived, divided about equally between British and American immigrants. About 65 per cent. of the immigrants arriving from the United States have been farmers, who for the most part, have settled in the prairie provinces. Thirty-eight per cent. of the total number from the United States made entries for homesteads in the west. About 30 per cent. of the European arrivals were farmers or farm labourers, according to the American Consul at Kingston, while 25 per cent. were classed as general labourers, and nearly the same percentage as mechanics. The influx of negroes has totalled a little over 400, while 5,200 Hindus have come to Canada. Of the British immigrants, approximately 500,000 have been English and Welsh, 150,000 Scotch, and about 45,000 Irish. Figures for other nationalities include, Austro-Hungarian 121,000, Italian 63,817, Russian 39,950, Swedish 19,349, German 21,146, French 16,236, Norwegian 13,798, Syrian 5,223. Western Canada received some 300,000 more immigrants than the eastern section. Saskatchewan and Alberta received more than half a million.

NOTES ON BOOKS.

LONDON HOUSES FROM 1660 TO 1820. A consideration of their architecture and detail. By A. E. Richardson and C. Lovett Gill. London: B. T. Batsford. 15*s.* net.

Although so many illustrated books about London have been published of late, Messrs. Richardson and Gill have found fresh ground to cultivate in the representation of the dwelling-houses situated in the old streets and squares, and they have

exhibited beauties likely to be overlooked by the casual passer-by. This, however, is not merely a book of pictures, as the examples are chosen in accordance with a systematic plan by which the years covered by the title are divided into three periods—(1) The Formative period, 1666-1720; (2) Middle or Palladian, 1720-1760; (3) Refined or Formal Classic, 1760-1820. The reason why these houses are so well worthy of notice is that they were produced by the chief architects of their times, such as Wren, Isaac Ware, Taylor, Chambers, the brothers Adam, Bonomi, Leverton, Soane, Nash, and Decimus Burton.

The West-End squares are amongst the chief glories of London, and the houses are here safer from interference than those in business quarters, but a very fine specimen of Adam's work—Harewood House, Hanover Square—has lately been destroyed to make room for the erection of a huge building. Two of the handsomest houses in St. James's Square—Lichfield House (No. 15), designed by "Athenian" Stuart, and Sir Watkin Wynne's house (No. 20) by Robert Adam—are both illustrated in this book. No. 15 has always been recognised for its beauty, whilst No. 20 was generally overlooked until the revival of interest in Adam's work. The latter is unpretentious, but its originality and charm are so considerable that possibly those who examine it carefully will prefer it to Stuart's more noted work.

Three of the plates are devoted to the Adelphi, and show an excellent doorway in John Street and the front of Alliance House in Adam Street, with an enlarged view of the lace-like balconies. The authors have produced a charming series of drawings of fanlights and balconies. The senseless destruction of some of these things in the nineteenth century is amazing. In Russell Square may be seen a house with a fanlight of one sheet of plate glass, and next door a beautifully designed fanlight like unto those figured by the authors. What must have been the standard of taste of those who replaced such a work of art by a plain piece of glass? The illustrations to this book, exhibiting the manifold beauties of many apparently commonplace houses will surprise even those who know London streets well, for they are shown designs which are well worth a pilgrimage to see.

H. B. Wheatley.

GENERAL NOTES.

The Swiss Hotel Industry.—The number of tourists who frequent the Swiss hotels ranges from 400,000 to 500,000 a year on an average, about 30 per cent. of whom are Germans, 20 per cent. Swiss, 15 per cent. English, 12 per cent. French, 6 per cent. Americans, 4 per cent. Russians, and 2 per cent. Belgians. These travellers, according to the Belgian Minister at Berne, expend on an average about ten shillings a day. During at least two months, beginning with the middle of December, the hotels of St. Moritz, Davos, Grindelwald, Adelboden, and Montreux are filled. Château d'Oex, Engelberg, Andermatt, and other parts, all have a winter season, as do also localities in the Jura mountains of Vaud. The influx of foreigners to the shores of Lake Geneva is explained by reasons of climate and the world-wide reputation of specialists who reside there, principally at Lausanne. The winter *clientèle* is composed chiefly of English and Germans. During the winter of 1909-10 English patrons formed 48 per cent., Germans 22 per cent., Swiss 14 per cent., French 6 per cent., Belgians and Dutch 3 per cent., Americans 3 per cent., Russians 1 per cent. Much money has been spent in the course of the last few years in the construction of new, and the enlargement of old, hotels, but there are no statistics in this regard later than for the year 1905. Statistics for that year show that the total capital engaged in the Swiss hotel industry was about £31,000,000.

Royal Sanitary Institute Congress, 1912.—The Royal Sanitary Institute have accepted an invitation from the City Council of York to hold their Twenty-seventh Congress and Exhibition in that city from July 29th to August 3rd, 1912.

Non-Ferrous Metals Exhibition.—An international exhibition of non-ferrous metals will be held at the Agricultural Hall, Islington, from May 6th to 18th, 1912, under the presidency of Sir Gerard Alfred Muntz, Bart., President of the Institute of Metals. This is the first exhibition entirely devoted to the display of non-ferrous metals, their alloys, the apparatus used in their manufacture, and their applications to commercial, scientific, and domestic purposes.

The World's Output of Coal, 1909.—According to the report recently issued by the Chief Inspector of Mines, the number of persons engaged in mining and quarrying throughout the world in 1909 was considerably over six millions. Of this total nearly one-fifth were employed in the United Kingdom and more than one third in the British Empire. More than half were employed in getting coal alone, Great Britain employing over 997,000, the United States 666,000, Germany 688,000, France 190,000, Russia 174,000, Belgium 143,000, Austria nearly 134,000, and India over 119,000. The world's total output of coal was 1,113,000,000 tons, the value of which is estimated at nearly £400,000,000. As compared with 1908, these figures show an increase of 45,000,000 tons in the output, but a decrease af £9,500,000 in the value.

The Banana Industry of Santiago de Cuba.—The production of bananas is second in importance among the agricultural industries of Santiago de Cuba. There are three districts where bananas are grown for export. Saetia, on Nipe Bay; Sagua de Tanamo, on Tanamo Bay, and in the region about

Baracoa. The plantings at Saetia and Sagua de Tanamo are on lowland along the valleys of the Yumuri and Tanamo Rivers. The soil is a deep loam, formed from the deposits of the rivers and streams flowing from the Mayari mountains on the south and from decomposed vegetation. At Baracoa, the plantings are in the valleys and on the mountain slopes. The soil is also a deep loam from a disintegration of the rocks and earlier vegetation. There has been a large decrease in banana growing for export during the last decade. Large areas devoted to that industry have been planted in sugar-cane, because greater returns are derived from land planted with cane, and because the fruit produced in Cuba cannot compete with that of the Central American States, the winters of Cuba being too cold and dry. All the bananas produced for export are sent to the United States.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, NOVEMBER 13...East India Association, Caxton Hall, Westminster, S.W., 4.30 p.m. Sir Roland K. Wilson, "Compulsory Education for India in the Light of Western Experience."

Sanitary Engineers, Caxton Hall, Westminster, S.W., 8 p.m. Sergeant Dunworth, "Camp Sanitation: My Experiences during the Annual Training, 1911."

Brewing, Institute of (London Section), Criterion Restaurant, Piccadilly, W., 8 p.m. Mr. L. Chew, "Mechanical Refrigeration and its Application to the Brewing Industry."

Post Office Electrical Engineers, at the Institution of Electrical Engineers, Victoria-embankment, W.C., 6 p.m. Mr. W. S. Mountain, "Departmental Contracts."

Surveyors, 12, Great George-street, S.W., 8 p.m. Opening Address by the President, Mr. W. Edgar Horne, M.P.

Mechanical Engineers, Storey's-gate, Westminster, S.W., 8 p.m. (Graduates' Section.) Mr. James Brander, "Modern Locomotives."

London School of Economics, Clare-market, W.C., 5 p.m. Dr. C. S. Loch, "State Insurance."

London Institution, Finsbury-circus, E.C., 5 p.m. Mr. S. L. Hughes, "Oddities in Parliament."

Architectural Association, 18, Tufton-street, S.W., 7.30 p.m. Mr. T. B. Fulton, "That the True Hope of Architecture lies in the Study of Good Modern Work."

TUESDAY, NOVEMBER 14...Sociological, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. Rev. Principal Garvie, "Contemporary Social Developments of Canada."

Asiatic, 22, Albemarle-street, W., 4 p.m. Sir Charles J. Lyall, "The Pictorial Aspects of Ancient Arabian Poetry."

Civil Engineers, 25, Great George-street, Westminster, S.W., 8 p.m. 1. Mr. A. H. Roberts, "The Loch Leven Water-Power Works." 2. Mr. F. B. Sonnenschein, "The Hydro-Electric Plant in the British Aluminium Company's Factory at Kinlochleven."

Photographic, 35, Russell-square, W.C., 8 p.m. (Traill Taylor Memorial Lecture.) Dr. W. Rosenhain, "Optical Glass."

Anthropological, 50, Great Russell-street, W.C., 8.15 p.m. Mr. R. W. Williamson, "The Mafulu Mountain People of British New Guinea."

Colonial, Whitehall Rooms, Whitehall-place, S.W., 8.30 p.m. Dr. G. R. Parkin, "True Imperialism."

WEDNESDAY, NOVEMBER 15...ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. Opening Address of the 158th Session by Lord Sanderson, G.C.B., Vice-President and Chairman of Council.

Meteorological, 25, Great George-street, S.W., 7.30 p.m. 1. Mr. C. Harding, "The Abnormal Summer of 1911." 2. Mr. W. Larden, "Notes on Solar Halos."

Incorporated Accountants (Students' Society), 50, Gresham-street, E.C., 6.30 p.m. Mr. C. T. Tunstall, "Some Points as to Deeds and other Instruments."

Auctioneers (Junior Members), 34, Russell-square, W.C., 7.30 p.m. Mr. E. F. Shepherd, "Conducting a Furniture Sale from Beginning to End."

Microscopical, 20, Hanover-square, W., 8 p.m. 1. Mr. J. E. Barnard, "A Geometric Slide Photomicrographic Apparatus." 2. Rev. Hilderic Friend, "British Enchytraeids. II.—The Genus Fridericia." 3. Mr. H. J. Grayson, Slides of Rock Sections.

United Service Institution, Whitehall, S.W., 3 p.m. Captain C. J. Burke, "The Airship as an Aid to the Solution of Existing Strategical Problems."

Mining and Metallurgy, at the Geological Society, Burlington House, W., 8 p.m. 1. Discussion on Mr. Eugene Coste's paper, "Fallacies in the Theory of the Organic Origin of Petroleums." 2. Discussion on Mr. H. S. Ball's paper, "The Economics of Tube-Milling." 3. Mr. H. R. Sleeman, "The Whim Well Copper Mine, West Pilbara, North-West Australia."

THURSDAY, NOVEMBER 16...Linnean, Burlington House, W., 8 p.m. 1. Dr. R. R. Gates, "Recent Researches on Œnothera." 2. Mr. G. C. Druce, "Some Floristic Results of the International Phytogeographical Excursion through the British Isles." 3. Mr. N. O. Macnamara, "Additional Observations on Peloria in the Foxglove."

Chemical, Burlington House, W., 8.30 p.m. 1. Messrs. T. S. Patterson and H. H. Montgomerie, "The Influence of Neutral Solvents on Velocity of Reaction. Part I.—Transformation of Anissynaldoxime in Various Solvents." 2. Mr. G. T. Morgan and Miss F. M. G. Micklethwait, "Organic Derivatives of Antimony. Part II.—The Orienting Influence of Antimonic Substituents in the Benzene Nucleus." 3. Mr. A. H. Salway, "Chemical Examination of Calabar Beans." 4. Mr. S. U. Pickering, "Copper Salts and their Behaviour with Alkalis." 5. Messrs. G. G. Henderson and R. Boyd, "Contributions to the Chemistry of the Terpenes. Part XII.—Synthesis of a Menthadiene from Thymol, and of a Dihydrodiethyl Benzene from Phenol."

London Institution, Finsbury-circus, E.C., 6 p.m. Mr. H. Beaumont, "Troyes."

Historical, 7, South-square, Gray's Inn, W.C., 5 p.m. Mr. C. K. Webster, "Some Aspects of Castlereagh's Foreign Policy."

China Society, Caxton Hall, Westminster, S.W., 8 p.m. Dr. Chao-chu Wu, "The Longevity of China."

FRIDAY, NOVEMBER 17...Illuminating Engineers, at the ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. 1. Report of Progress during the Vacation, by the Honorary Secretary. 2. Dr. H. R. B. Hickman, "Notes on the Design of Motor-Car Headlights."

Brewing, Institute of (Yorkshire and North-Eastern Section), Queen's Hotel, Leeds, 7.30 p.m. Mr. Harold Wager, "The Dual Nature of the Yeast Plant Nucleus."

Mechanical Engineers, Storey's-gate, Westminster, S.W., 8 p.m. 1. Discussion on paper by Messrs. E. M. Eden, W. N. Rose, and F. L. Cunningham, "The Endurance of Metals: Experiments on Rotating Beams at University College, London." 2. Mr. J. H. Wicksteed, "Double-Cutting and High-Speed Planing Machines."

CONTRIBUTIONS TO THE READING-ROOM.

The Council have to acknowledge, with thanks to the Proprietors, the receipt of the following Transactions of Societies and other Periodicals.
